ABSTRACT OF THE DISSERTATION

The Use of Single-Molecule DNA Nanomanipulation to Study Transcription Kinetics

by CHEN-YU LIU

Dissertation Director:

Dr. Richard H. Ebright

Transcription involves many reaction steps and intermediates. Many phenomena in transcription kinetics are covered by ensemble average. Single-molecule DNA nanomanipulation techniques uncover these transcription kinetic events via determination of a transcription bubble in real time. In this dissertation, we focus on the transcription kinetics of bacterial RNAP. The study of transcription kinetics in this thesis can be divided into 4 main subjects: 1) The study of abortive initiation

mechanism: Through a single-molecule DNA nanomanipulation technique, we tested the three models proposed for the mechanism of abortive initiation - inchworming, scrunching and transient excursion - on T5 N25 promoter. Of the three models, only the scrunching model involves a change in the size of the transcription bubble during abortive initiation, which was observed by single-molecule DNA nanomanipulation technique.

2) The study of the kinetics of elongation and termination: By introducing varying transcribed region lengths into DNA templates, the kinetics of elongation and terminator rewinding were studied. The resulting kinetics, determined by the single-molecule nanomanipulation technique, was analyzed by different regression methods. In the normal regression, the elongation velocity is 10 b/s and terminator rewinding takes 3.4 s on a *tR2* terminator. Contrarily, through Poisson regression, the elongation velocity ranges from 6.4 b/s to 12.5 b/s and terminator rewinding takes 11.9 s on a *tR2* terminator.

3) The study of a promoter sequence's effect: The effect from sequence of the T5 N25 promoter and T5 N25 antiDSR promoter in transcription was evaluated. The transcription bubble sizes of open complex and initial transcribing complex using the T5 N25 antiDSR promoters are larger than the ones from the T5 N25 promoter. The difference in the two promoter sequences does not have an effect on the transcription bubble size of an elongation complex. And elongation and terminator rewinding kinetics are not

affected. On the other hand, abortive initiation and promoter escape are affected by the difference in the promoter sequence. 4) The study of the effect of transcription factor-GreB: The effect of transcription factor-GreB on abortive initiation was evaluated by the single-molecule DNA nanomanipulation technique. GreB does not affect the transcription bubble size during abortive initiation, but does reduce the lifetime of initial transcribing complex.

Acknowledgements

I am grateful for many people who assisted me to finish this dissertation. For the past several years, my work has become a part of my life. Many people who involved in my work also involved my work.

First, I would like to thank my advisor Dr. Richard Ebright. He supported me on many aspects from my daily life to study. He not only provided me the environment to study but also give me a lot of guidance on study. Without his support, I could not have such a great experience in life and study and my whole life will be quite different. I do not know how to express how grateful I am to him.

I would like to thank Dr. Yon Ebright. She solved many problems for me. Without her assistance, my study can not proceed.

I also thank Dr. Terence Strick. He taught me how to operate the single-molecule DNA nanomanipulation technique, which I used to study some interesting research objects. Also, he helped me to accommodate the life in Paris.

I thank Dr. Ronald Levy. Without his kindness, I could not join BioMaPS program and graduate smoothly.

I thank Dr. Richard Ludescher for spending time on correcting my dissertation and gave me the valuable comments.

I thank Dr. Wilma Olson. She also gave me some valuable comments on the dissertation.

I thank Jayanta Mukhopadhyay being kind and generous to me always.

I thank Charles O'Brien for being kind to provide any kind of assistances from correction of thesis, giving me accommodation, sharing experience with me...

I thank Dongye Wang, Kerri-Ann Norton, Jianxi Xiao, Hongjun Zhang and David Degen, for assistance in my dissertation and making my life more interesting during the past several years.

In the end, I would like to thank my family- my mother and my sister- for your

patience and support.

To the memory of my father,

Ming Liu

Curriculum Vita

Chapter 1

Introduction

1.1 RNA Polymerase

RNAP (RNA polymerase) plays an essential role in gene expression; it can transcribe DNA sequences into RNA that can be translated into proteins that carry out many cellular functions. RNAP can be categorized into two types: multiple subunit RNAPs and single subunit RNAPs. Multiple subunit RNAPs are highly conserved in their sequences and structures and are found in prokaryote or eukaryote cells. By contrast, single subunit RNAPs are found among bacteriophages or mitochondria [1]. Although the sequences of the multiple subunit RNAP family are quite different from the sequences of the single subunit RNAP family, they still have very similar functions and structure. Many of the studies of multiple subunits RNAPs have relied on studies from the single subunit RNAP family.

Many papers have focused on *Escherichia coli* RNAP, even though the structure of *Escherichia coli* RNAP is not available yet. Most studies of the RNAP

structure – function relationship of *Escherichia coli* RNAP rely on the X-ray structure of *Thermus aquaticus* RNAP and *Thermus thermophilus* RNAP. This is because the structures of RNAPs of the two species have high similarity with *Escherichia coli* RNAP, so they can be predicted to have similar structure-function relationship.

Bacterial RNAP core enzyme is composed of five subunits: β , β' , α , α' and ω . In order to carry out transcription on DNA, core RNAP needs to combine with a σ (sigma factor) to recognize a promoter DNA sequence and start transcription. A core RNAP incorporating with a sigma factor is called a holoenzyme. Different sets of sigma factors can initiate different sets of gene expression that help the cell accommodate to its environment.

Bacterial sigma factors can be classified into two categories- one is σ^{70} and other is σ^{54} . σ^{70} associates with most house keeping genes of *Escherichia coli* and is well characterized. The σ factor can be divided into four regions- $\sigma 1$, $\sigma 2$, $\sigma 3$ and $\sigma 4$ with flexible linkers in between some regions.

1.1.1 Promoter

A promoter is a DNA sequence by which an RNAP can initiate transcription.

The promoter sequence can be composed of two hexamer elements : – 10 element and -35 element. The -10 and -35 refer to the center of two hexamer elements located at upstream 10 and 35 nucleotide of transcription start site [2,3]. Between the two elements is a spacer around 17 bp which can also determine the binding capability of RNAP on a promoter by its length [4,5]. In addition, a subclass of promoters lacks a –35 element but has an extra extended –10 element to assist RNAP binding [6,7]. For these promoters, they can also have an upstream element between -40 and -60 which can enhance the binding of RNAP and promoter by interaction with α subunit of RNAP [8-10].

1.1.2 Introduction of Structure

The crab-claw shape like multiple subunit bacterial RNAP holoenzyme has dimensions of $\sim 150 \text{ \AA} \times \sim 100 \text{ \AA} \times \sim 100 \text{ \AA}$. The beta and beta primer domain form two pincers of the claw. The active site is the cleft between the two pincers. The structure of RNAP holoenzyme is shown in (Figure 1-1).

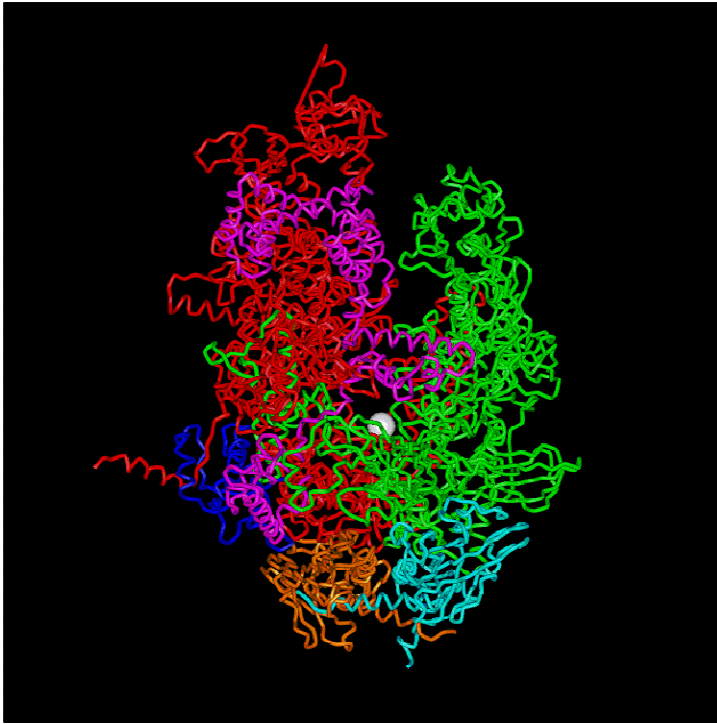

Figure 1-1.

The Crystal structure of *Thermus aquaticus* RNAP Holoenzyme:

The α Subunits: Orange and Light Blue, the β Subunit: Green, the β' Subunit: Red, the ω Subunit: Blue, the σ Subunit: Magenta. The magnesium ion in the active site: White. The beta and beta primer domain form two pincers of the claw. The active site is the cleft between the two pincers [11].

1.2. Transcription

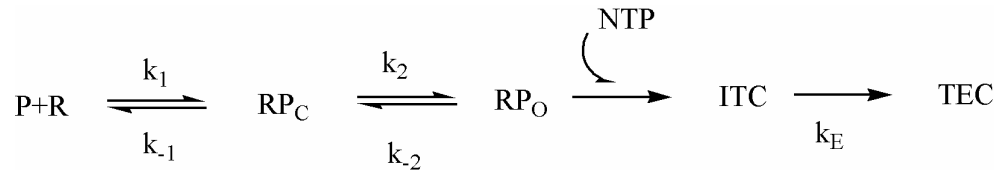

Generally speaking, the transcription process can be divided: promoter search, initiation, elongation and termination.

1.2.1 Promoter search

Since RNAP is responsible for transcribing genes in vivo, it needs to bind onto a promoter. Through diffusion, RNAP can target a promoter in solution. There are different modes of diffusion that can take place, these include 1D diffusion-sliding along DNA and 3D diffusion - hopping and intersegment transfer. It has been demonstrated that RNAP can slide along DNA [12], however, 1D diffusion may not be an efficient way for RNAP carrying out transcription of a gene because thermal diffusion has a probability to go in the reverse or the forward direction. Moreover, 1D diffusion works for short range movement. On the other hand, the protein-ligand association rate is on the order of $1 \times 10^8 M^{-1} s^{-1}$ which is close to the diffusion limit [13]. If 3D diffusion is the only mechanism for a protein to target a specific site on a DNA, the protein-ligand association rate would be much lower than $1 \times 10^8 M^{-1} s^{-1}$ [14]. Therefore, the promoter search of RNAP could be achieved by both 3D and 1D diffusion among DNA [15,16]. At low salt condition, a protein may only traverse along the DNA, while in vivo, it may have two diffusion modes [17]. The RNAP searches a promoter through 1D and 3D diffusion and when it finds the promoter site, initiation starts.

1.2.2 Initiation

The kinetic scheme of RNAP transcription initiation is shown in scheme 1-1.

Scheme 1-1

When the RNAP holoenzyme (R) arrives at a promoter (P); it can associate with a promoter, forming a closed complex- RP_C , it does this at rate k_1 . The closed complex can dissociate from the promoter, which happens at rate k_{-1} . Thus, the formation of closed complex is a reversible reaction and can be characterized by K_B (k_1/k_{-1}) on the order of $3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1} \sim 3 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ [18]. Following the formation of closed complex, $\sigma 2$ region on the holoenzyme nucleates DNA unwinding at -10 element of a promoter and separates the double stranded DNA from -11/-12 to +3/+4, isomerizing the closed complex into an open complex- RP_O [19]. This step can be described with kinetic rate of k_2 . Usually, for some strong promoters, the open complex formation is very stable, the reverse reaction being negligible (k_{-2} is very small.). The formation of open complex causes the change of RNAP

holoenzyme conformation. The DNA enters the two pincers of RNAP. The two pincers then close down, clamping DNA in place. The DNA between position -11 to +3 unwinds and the strands separate. Then each strand passes through the channels formed by β and β' domain [20]. The $\sigma 1.1$ domain- a DNA mimic- is displaced from the DNA binding domain which is formed by the two pincers [21,22]. A model of the structure of open complex of *Thermus thermophilus* is shown in Figure 1-2.

Figure 1-2

The model structure of *Thermus aquaticus* RNAP Holoenzyme: The template DNA: Yellow, Magenta, the α Subunits: Orange and Light Blue, the β Subunit: Green, the β' Subunit: Red, the ω Subunit: Blue. The two pincers of β and β' clamp and bend the promoter DNA, the promoter DNA is separated into two single strands of DNA [23].

Upon the formation of open complex, binding of NTPs which are complementary to the initiating sequence can further stabilize the open complex

without formation of phosphodiester bond [24]. With a supply of NTPs, the RNAP can start initiation transcription.

When transcription initiation begins, RNAP enters into a cycle of synthesis of nascent RNA fragments and aborts RNA products from 2 nt~10 nt long(or up to 15 nt at some promoters) until the RNAP escapes from the promoter- a stage called abortive initiation state. The rate in which RNAP leaves from the abortive initiation state is characterized as k_E (scheme 1-2). The complex is called initial transcribing complex (ITC). Not all ITC can generate full length of RNA transcripts, only some of these ITCs can transcribe full length of RNA after many cycles of transcribing and releasing nascent RNA [27,28]. NTPs diffuse through the secondary channel into the active site of RNAP, annealing with the template DNA sequence. Afterward the pyrophosphate group on the NTP is hydrolyzed and the NMP is incorporated into the RNA transcript. This active center will keep moving relative to the template DNA and incorporating nucleotides on the RNA products. As the length of the nascent RNA transcript increases, it encounters the linker between σ_3 and σ_4 [25]. Either the linker of σ_3 and σ_4 releases from the RNA exit channel or the RNAP releases the nascent RNA through secondary channel [26].

Many factors can affect or regulate the transcription at the abortive initiation stage like the sequence of a promoter, transcription factors, concentration of NTP and concentration of salt, etc. These factors may also play a role in gene regulation. For instance, by transcribing with ITS (initial transcribed sequence), RNAP can produce various lengths of nascent RNA products with different abortive probability and productive ratio. The productive ratio can be increased by the presence of some cleavage factors like GreA and GreB or by an increase in NTPs concentration [29-32].

There have been three proposed mechanisms for RNAP starting abortive initiation- the inchworming model, transient excursion model and scrunching model in Figure 1-3 [33-35].

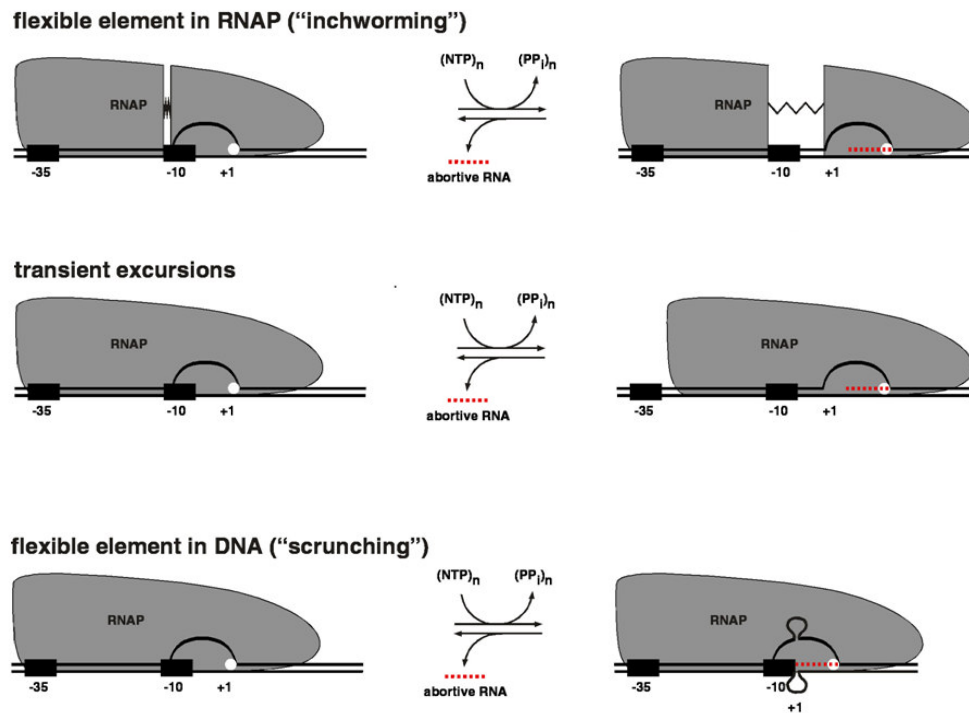

Figure 1-3

**The proposed mechanisms for abortive initiation and promoter escape:
Figure from reference [36].**

These models are based on the observations that abortive initiation nascent RNA has a length of 9~10nt and that upstream boundary DNA is protected during abortive initiation. That is found from the footprint experiments. The inchworming model states that abortive initiation is involved in the movement of RNAP active center without release of the binding of RNAP at -35 element while the RNAP synthesizes nascent RNA. The transient excursion model proposes that RNAP synthesizes abortive RNA transcripts and leaves promoter, aborting the RNA transcript and moving back to the promoter. As for the scrunching model, it

proposes that the DNA may scrunch into RNAP without breaking the upstream contacts of the RNAP with the promoter during abortive initiation [37].

1.2.3 Elongation

After RNAP escapes from a promoter and starts elongation, RNAP can extend the RNA product when entering elongation stage [38]. A single NTP is brought into the active site through the secondary channel and binds at the substrate binding sub-site next to the 3' terminal of RNA. The RNAP removes the pyrophosphate from the NTP and incorporates the NMP into the RNA by the formation of phosphodiester bond with the 3' terminal of the RNA. Afterward, the translocation of 3' terminal of the RNA is triggered by the G trigger loop and the bridge-helix of RNAP [39]. A DNA base pair rewinds at the upstream of the transcription bubble and a DNA base pair is flipped out on the downstream of the bubble when the translocation of the RNAP occurs (Figure1-4). After the translocation of transcription bubble, the substrate binding sub-site is empty again for the next coming NTP. The single nucleotide addition cycle will continue until RNAP terminates RNA synthesis [40].

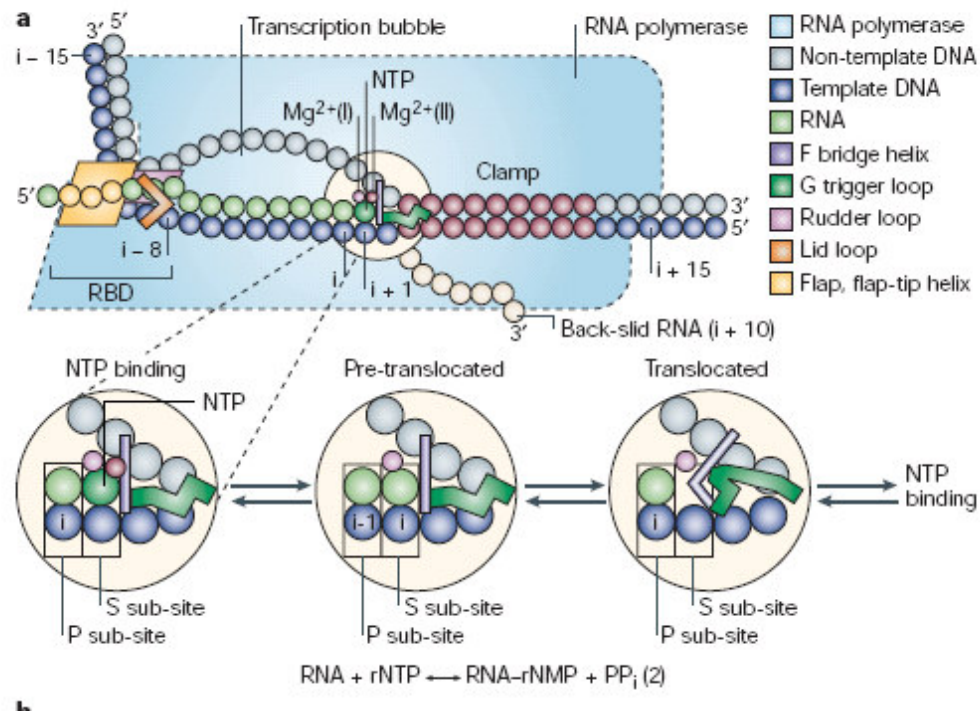

Figure 1- 4

The single nucleotide binds at the substrate binding sub-site followed by the hydrolysis of NTP. Afterward, the G loop triggers the bending of the bridge –helix, and the RNAP translocates forward, starting next cycle of RNA synthesis. Figure from ref [41].

1.2.3.1 Pause state

In the elongation state, RNAP sometimes stalls at template DNA for several seconds to one minute, which is called pause. These pause events in the RNAP elongation can be put into two categories- Class I pauses and Class II pauses. The Class I pauses are caused by a RNA hairpin. Thus, the Class I pauses are resistant to GreA and pyrophosphate [42]. Addition of an oligonucleotide which is

complimentary to the pause hairpin can reduce Class I pauses. The Class II pauses are caused by weak DNA:RNA hybrids, which are sensitive to GreA and pyrophosphate. The Class II pauses may result in the backtracking of RNA transcript of TEC. And the Class II pauses are also called an arrested state [43].

When the backtracking of RNA transcript occurs, the RNA protrudes downstream from the active site into secondary channel. The protruded RNA can be cleaved by transcription factors like GreA and GreB.

1.2.3.2 Two functional Magnesium ions

The two functional Mg^{2+} need to be bound to the active site of RNAP. MgI is tightly bound to the active site but not MgII. Without MgII the RNA can not be synthesized properly. The GreA and GreB serve a role in helping chelation of the MgII in the active site of RNAP.

1.2.4 Kinetics

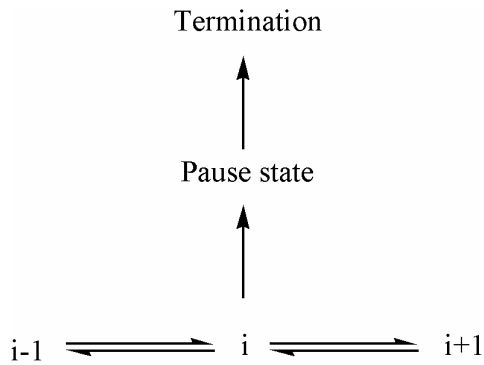

Both a power stroke model and a Brownian ratchet model have been proposed for transcription elongation [44]. The power stroke model emphasizes that the conformation change of RNAP in elongation is involved in the translocation of the

RNAP along the DNA, which converts the energy of NTP incorporating into RNA transcript to the mechanic driving force of RNAP translocation [45].

On the other hand, the Brownian ratchet model proposes that TEC (transcription elongation complex) can slide along DNA by thermal fluctuation and is biased by nucleotide incorporation.

In the Brownian ratchet model, the transcription kinetics for each template position of RNAP can be regarded as a competition among various reaction pathways (Scheme 1-2). RNAP must reach a state at which RNAP can choose to enter a pause/backtracking state, pyrophosphorolysis or an editing state.

The energy difference between these states can be small. Therefore, an increase of the pyrophosphate concentration may reverse the elongation reaction. However, shortening a RNA product does require 100 fold increase of the concentration of pyrophosphate in vivo [46].

Scheme 1-2

1.2.4.1 The thermal stability of TEC

The thermal stability of TEC can be applied in the ratchet model quantitatively.

The thermodynamic stability of TEC can be expressed as the sum of interaction energy between DNA, RNA and protein. The $\Delta G^\circ_{\text{(bubble)}}$ is responsible for opening the double stranded DNA. The $\Delta G^\circ_{\text{(hybrid)}}$ represents the stabilization from an 8-9 bp DNA-RNA hybrid [47]. As for the $\Delta G^\circ_{\text{(RNA polymerase)}}$, it comes from the interaction between the RNAP and the DNA or the RNA [48]. By an assumption of the $\Delta G^\circ_{\text{(RNA polymerase)}}$ being constant during elongation, the variation of thermal stability of TEC along the template DNA can be determined by the $\Delta G^\circ_{\text{(bubble)}}$ and the $\Delta G^\circ_{\text{(hybrid)}}$, which determines the kinetic behavior of transcription in a manner of sequence dependence like termination and backtracking [49-51].

This assumption of a constant $\Delta G^\circ_{(\text{RNA polymerase})}$ is based upon two factors: the first one is nonspecific interaction of the RNAP with the DNA and the RNA and the second one is that two terms: $\Delta G^\circ_{(\text{bubble})}$ and $\Delta G^\circ_{(\text{hybrid})}$ have to be comparable with $\Delta G^\circ_{(\text{RNA polymerase})}$.

1.2.5 Termination

The transcription termination can occur with a termination factor or intrinsically. The transcription termination which requires termination factors can be divided as Rho-dependent transcription termination or Mfd-dependent transcription termination. Rho-dependent transcription termination relies on an ATP driven termination factor called Rho factor. Rho factor is a RNA dependent ATPase and RNA translocase which can unwind the DNA-RNA hybrid and terminate the synthesis of RNA [52,53]. By loading onto the cytosine rich site at the RNA transcript and moving in 5' to 3' direction, the Rho factor can catch up when the TEC stalls at pause site [54]. The Rho factor pulls out the RNA transcript from the TEC, and the RNAP dissociates from the DNA.

Mfd-dependent transcription termination also depends on an ATP driven

termination factor, which is called Mfd ATP dependent DNA translocase. Mfd can rescue a backtrack or arrested complex into TEC in the presence of full set of NTP. In the absence of NTP, Mfd can cause the dissociation of RNAP or the release of transcript [55]. Mfd has two domains related to its RNAP release activity: a RNAP binding domain and a DNA translocase domain. The DNA translocase domain contacts with around 25 bp of the upstream duplex DNA of transcription bubble. A study has suggested that Mfd-RNAP complex may exert force on transcription bubble, which causes transcription bubble move forward [56].

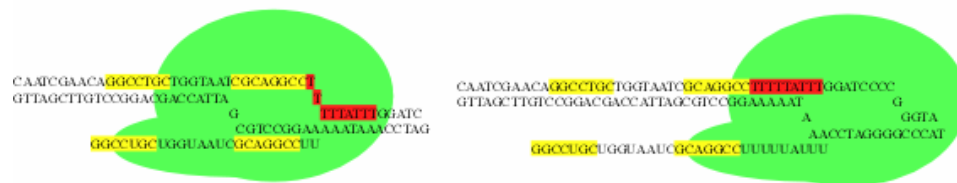

In the case of intrinsic termination, when RNAP arrives at a particular DNA sequence called a terminator, the RNAP is likely to stop elongation and release itself from the template DNA otherwise the RNAP may run off the terminator. A terminator has an invert repeat sequence and a poly A sequence. The invert repeat sequence can be transcribed into a hairpin and the sequence is followed by a poly A tract which triggers transcription termination. Different terminators have different efficiencies in termination of RNA synthesis [57].

In the case of deleting half of the invert repeat sequence of a terminator, the termination event will not occur while RNAP transcribes the modified terminator.

However, upon addition of complimentary oligonucleotide, the termination occurs by annealing of the oligonucleotide with the RNA transcript. The annealing of the oligonucleotide and the RNA transcript functions like a termination hairpin.

Two models have been proposed for termination mechanism: forward translocation model [58], allosteric model [59,60](Figure 1-5).

Forward Translocation Model

Allosteric Model

Figure 1-5

In the forward translocation model, termination occurs when RNAP stops RNA synthesis and the transcription bubble translocates forward. In the allosteric model, the termination hairpin causes the long range conformation change of RNAP, which terminates the synthesis of RNA.

In the forward translocation model, when transcription termination event occurs,

RNAP stops incorporating nucleotides into RNA transcript and the upstream DNA of transcription bubble rewinds and the downstream of transcription bubble unwinds.

The transcription bubble moves forward. Since in the model the unwinding of the downstream of transcription bubble requires a torque, termination factor may play a role in providing the torque. From a recent study, the substitution of nucleotide on the non template DNA will affect the Rho and Mdf to mediate RNA release [61]. It indicates that the substitutions prevent rewinding of the transcription bubble by the termination factors.

In the case of intrinsic termination, the DNA rewinding torque can be generated by the formation of a termination hairpin or the annealing of oligonucleotide with the RNA transcript of a terminator in which the half stem sequence of a termination hairpin has been removed. It was found that blocking downstream double stranded DNA of a terminator can prevent termination [62]. The termination can be caused by altering the sequence of non template DNA of a terminator or the upstream sequence of the non template DNA of a terminator [63,64].

In the allosteric model, the transcription termination involves the long range conformation change of RNAP by some terminator factors to trigger the release of the

RNA transcript from TEC [65,66].

Summary

RNAP can carry out transcription. The stages of transcription can be divided into promoter search, initiation, elongation and termination. In the initiation stage, RNAP forms a closed complex at a promoter. Afterward, the closed complex forms an open complex, which is a complex having double stranded promoter DNA separated by RNAP. Upon providing NTPs, the open complex can transform to ITC. The ITC can transform into TEC while the RNAP escapes from the promoter. The efficiency of promoter escape can be determined by the ITS. During elongation, RNAP may be trapped in an arrested state and pause state. The kinetics of elongation can be described in terms of the thermal stability of TEC, which is affected by the sequence of transcribed region, the concentration of nucleotides and the transcription factors.

Chapter 2

Methods for the study of transcription with single-molecule technique

2.1 Previous studies of the transcription kinetics with the single-molecule technique

Transcription reaction involves many steps and reaction pathways, and is highly heterogeneous and asynchronous. Most results from bulk measurements only reflect an ensemble average of intermediate states and parallel reactions, many phenomena are included in the ensemble average. Thus, there is a need for the use of single molecule technique to uncover the reaction intermediates and the reactions in transcription. The single-molecule technique provides an opportunity to observe the distribution of the reaction intermediates and study the transcription mechanism of each single reaction step. Below is the brief review for the single-molecule techniques used in the study of RNAP transcription.

2.2 Atomic force microscopy (AFM)

AFM has been adopted in determining the position of RNAP along DNA as a function of time. However, surface adsorption in the AFM measurement affects the kinetics of RNAP on DNA molecules. In addition, AFM also has been used to measure the bending of DNA by formation of open complex and elongation complex of RNAP. It has been shown that in an open promoter complex, the DNA bend angle varies from $55\text{-}88^\circ$ and contour length is reduced by $\sim 30\text{ nm}$ [1;2]

2.3 Tethered Particle Motion Method

The tethered particle motion method has been used in study of transcription elongation [3;4], where RNAP is immobilized on a glass surface, and the RNAP is bound to a DNA molecule at one end, and a streptavidin coated particle (or an avidin coated bead) is tethered by the other end of the DNA molecule through biotinylated nucleotides. The RNAP transcribes in the direction of the tethered particle or the opposite direction, depending on the orientation of a promoter. As the RNAP transcribes in the direction of the tethered particle, the contour length of DNA between the tethered particle and the immobilized RNAP is reduced, whereas if

RNAP transcribes in the opposite direction it is increased. The magnitude of Brownian motion of the tethered particle is correlated with the length of the tethering DNA. Thus, by monitoring the Brownian motion of the tethered particle with light microscopy and digital image processing, the tethering DNA length is evaluated. However, the temporal and spatial resolution of this method is limited by the Brownian motion. At the tether length of 308 bp and 1915 bp, it has an accuracy of 108 bp and 258 bp r.m.s., respectively. The shorter the tether length, the more precision can be obtained and less acquisition is required. The method has been used in determination of elongation velocity of RNAP at 15 bp s^{-1} (Figure 2-1) [4].

Tethered particle low-control Microscopy

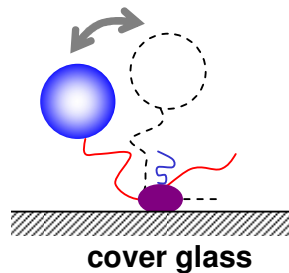

Figure 2-1

The RNAP is immobilized on the glass surface and bound to a DNA molecule, which tethers a streptavidin coated particle (or an avidin coated bead). Through the Brownian motion of the particle or bead, the tethered DNA length is evaluated.

2.4 Flow-control video microscopy

Tethered particle method could be modified by introducing an external force on a tethered bead. That can be done by immobilizing RNAP on a bead, capturing the bead by a micropipette and introducing a constant flow to apply an external force on the DNA tethered bead (Figure 2-2) [5;6].

Flow-control video Microscopy

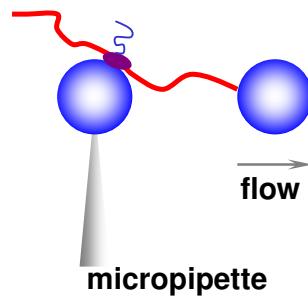

Figure 2-2

The RNAP is immobilized on a bead which is captured by a micropipette. The RNAP is also bound to one end of a DNA molecule which tethers another bead in the other end. An external force is applied on the DNA linking bead through a flow.

2.5 Optical tweezers with rotation detection

By attaching fluorescence labeled beads to an optically trapped DNA tethered particle and immobilizing the RNAP on a glass surface, it is observed that the tethered

particle rotates while the RNAP transcribes the tethering DNA. The results suggest the rotation of tethered particle is driven by RNAP groove-tracking while sliding along a DNA molecule. Since the sliding of RNAP along a DNA molecule is involved with groove-tracking, RNAP rotates along the helical axis of the DNA molecule and thus the movement of RNAP along a DNA molecule is longitudinal and rotational, too.

However, it is difficult to observe these events by this method because of Brownian motion of tethered particles, low binding possibility of RNAP, short lifetime of promoter search and two different rotation directions of tethered particles (Figure 2-3) [7]. The observation can be deviated by the Brownian motion. The low binding possibility of RNAP, short lifetime promoter search and two different rotation directions of tethered particles results in a few distinguishable events in observation.

Optical tweezers with rotation detection

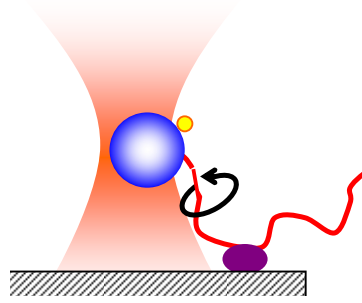

Figure 2-3

The RNAP is immobilized on a glass surface and bound to a DNA molecule. The DNA molecule tethers a bead at one end, and the fluorescence labeled beads are attached to the DNA tethered bead. An external force is applied on the DNA tethered bead through optical trapping.

2.6 The combination of total internal reflection fluorescence (TIRF) with optical trapping

In TIRF, there are two beads which are attached on the two ends of a DNA molecule which is aligned by fixing two beads with two optical traps. The position of fluorescence labeled RNAP sliding along the DNA molecule is determined. It is found that RNAP prefers to bind AT rich sequences rather than GC rich sequences of DNA. The association constant for the DNA binding is around $10^{-3} bp^{-1} M^{-1} s^{-1}$. From the rate of dissociation and association to a DNA molecule, the diffusion constant of RNAP along the DNA is obtained as $10^{-10} cm^2 s^{-1}$. Nevertheless, the method could not distinguish other binding species like open complex or closed

complex. The estimated diffusion constant is 3 order lower than other studies [8-11].

This may be due to the low spatial resolution ($0.2\mu\text{m}$) which causes underestimation of the diffusion constant (Figure 2-4).

The combination of the total internal reflection fluorescence (TIRF) with optical trapping

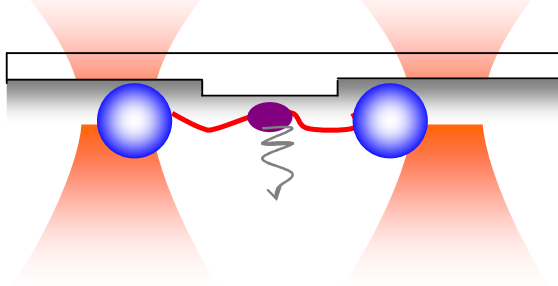

Figure 2-4

In TIRF, a DNA molecule is bound to two beads which are optical trapped. The position of fluorescence labeled RNAP can be determined. The diffusion constant is obtained through the position of RNAP with time.

2.7 Dual optical tweezers

In the dual optical tweezers method, one end of the DNA is anchored on a bead; another end of the DNA tethers a RNAP molecule which is immobilized on a bead. This could also be achieved by optically trapping the tethered beads [3]. In order to reduce the Brownian noise and increase the position stability, the whole experimental apparatus can be placed in helium rather than in the air. The helium

gas can reduce the deflection of laser beam. The lower deflection of laser beam increases the positional stability. In this method, the spatial resolution is able to reach the angstrom level.

Through this experiment setup, it has been demonstrated that RNAP is able to incorporate single nucleotides into the RNA product one by one. The elongation dynamics is determined by applying assistant load and hindering load on the RNAP. By fitting the dynamics into both a Brownian ratchet model and a power stroke model, it has been demonstrated that RNAP elongates along DNA in the Brownian ratchet mechanism (Figure 2-5) [12].

Dual optical tweezers

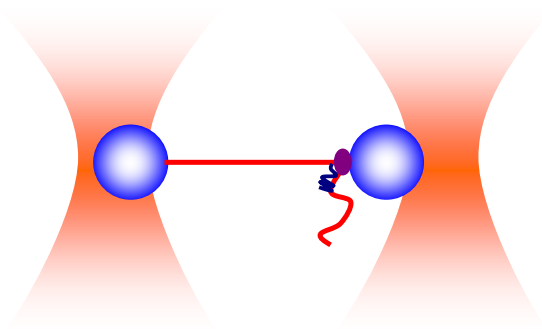

Figure 2-5

In the dual optical tweezers method, one end of the DNA is anchored on a bead. Another end of the DNA tethers a RNAP molecule which is immobilized on a bead.

Summary

The single-molecule technique has been used in uncovering the phenomena behind the ensemble average. Transcription is highly heterogeneous and involves many reaction pathways and intermediates. Atomic force microscopy is used in determining the position of RNAP and the conformation of DNA molecules, but it has a disadvantage of surface interaction between surface and RNAP. Tethered particle motion method is used in determining the tracking of RNAP along DNA molecule. Brownian motion causes deviations for the determination of RNAP position along the DNA molecule. The flow-control video microscopy can overcome the Brownian motion problem by exerting an external force on the bead. Or optical trapping can be used to fix the bead in detection of RNAP's groove-tracking and reduce the Brownian motion. In addition, the combination of total internal reflection fluorescence (TIRF) with optical trapping has been used in determination of diffusion of RNAP along the DNA molecule. The dual optical tweezers can be used in determining the kinetics of elongation in the resolution of angstrom.

Chapter 3

Single-molecule DNA nanomanipulation

Single-molecule DNA nanomanipulation is a technique used to study DNA-protein interactions upon the change of topology of a DNA molecule. The single-molecule DNA nanomanipulation experiment geometry is shown in Figure 3-1.

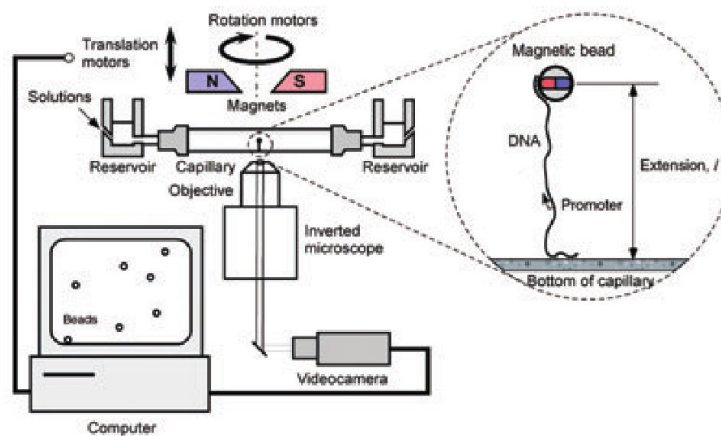

Figure 3-1

The instrument setup of the single-molecule DNA nanomanipulation experiment
Figure from ref [1]

3.1 Experimental setup

A microscope with CCD camera is used to collect the images of beads that are processed and analyzed by a computer after collection. The camera collects images

at a rate of 33 Hz. The objective of the microscopy is bound onto a piezo driver, which is able to adjust the object's z axis position with tens of nanometers precision (Figure 3-1). After injection of the polystyrene beads through a pair of reservoirs, the beads are deposited and attached to the surface of the capillary. The polystyrene beads serve as a reference for relocating the focal plane on the polystyrene coated glass surface.

DNA-paramagnetic beads are injected after the polystyrene beads and then sedimentation occurs. After sedimentation, the antidigoxigenin on the plastic surface grasps one end of DNA which is labeled with digoxigenin (Figure 3-2). The other end of this DNA is biotinylated and attached on the streptavidin coating paramagnetic bead.

Above the paramagnetic bead-anchored DNA is a pair of magnets which apply an external mechanical force on the DNA molecule through the paramagnetic bead. The magnets are mounted on a rotor, which could change the orientation of the magnets. The rotor is attached to a motor which is able to adjust the z axis position of the rotor and magnets (Figure 3-1).

Since the gradient of the magnetic field created by the magnets changes little on the micrometer scale and is parallel to the surface, the change in force due to the change of the DNA extension can be neglected. However, at the difference of millimeter scale, the gradient of magnetic field decays exponentially, which has an effect on the magnitude of force applied on the magnetic beads. Thus, changing the z axis position of the magnets in millimeter scale alters the magnitude of the magnetic force on the paramagnetic beads. In addition, the magnetic force also depends on the size of the paramagnetic beads. Generally, a bead with a radius of 1.5 micrometers can generate a force up to 50 pN.

3.2 Preparation of DNA

The DNA molecule used in our current experiment setup is around 2kb and is obtained by PCR from a plasmid. The two ends of this DNA fragment contain restriction enzyme sites. After treating the DNA with restriction enzyme, the two ends of the 2kb DNA are ligated with two 1kb DNA fragments, which have biotin and digoxigenin labeled nucleotides, respectively (Figure 3-2). After ligation, the two ends of the DNA are bound to the surface of the capillary and the paramagnetic bead with antidigoxigenin and streptavidin, respectively.

Figure 3-2
The basic DNA construct

3.3 Determination of the position of a bead

In order to determine the position of a bead, an image is recorded and this image is analyzed. The image for a bead in the capillary has concentric optical diffraction rings (Figure 3-3-a). The x, y position of the bead is determined by the center of the diffraction ring, which is obtained by the following procedures. The image has a diffraction ring located at $X(0)$, $Y(0)$ at time equal to zero ($t=0$). The $X(t')$ position of the bead at time equal to t' ($t=t'$) can be obtained by carrying a FFT (fast Fourier transform) correction of inverse image intensity profile along $X=X(0)$ and relative to $Y=Y(0)$ (Figure 3-3c) with the new image intensity profile. The FFT correction of two image intensity profiles can have a maximum value by translating the inverse intensity profile by δy . $Y(t')=Y(0)+\frac{1}{2}\delta y$. Using this method, one can also obtain $X(t')$. The bead's new position $X(t')$, $Y(t')$ is determined from a

previous position of $X(0)$ and $Y(0)$.

Before determining the z position of a bead, it is required to have a reference for the change of radius of optical diffraction ring along the z axis of focal plane which is relative to the objective of the microscopy. In order to make the reference, the objective has to move down 300nm for a couple cycles and take an image at the focus plane with various z positions. This step is necessary to determine the radii of rings with various z positions of the object. The radii of the diffraction ring are linearly correlated with z positions of object. In other word, the radii of the diffraction rings are proportional to the distance between the objective and the bead which we are observing. Therefore, as the objective is fixed, the z position of a bead which is relative to objective could be determined by the radii of its diffraction rings from this linear correlation (Figure3-3-b).

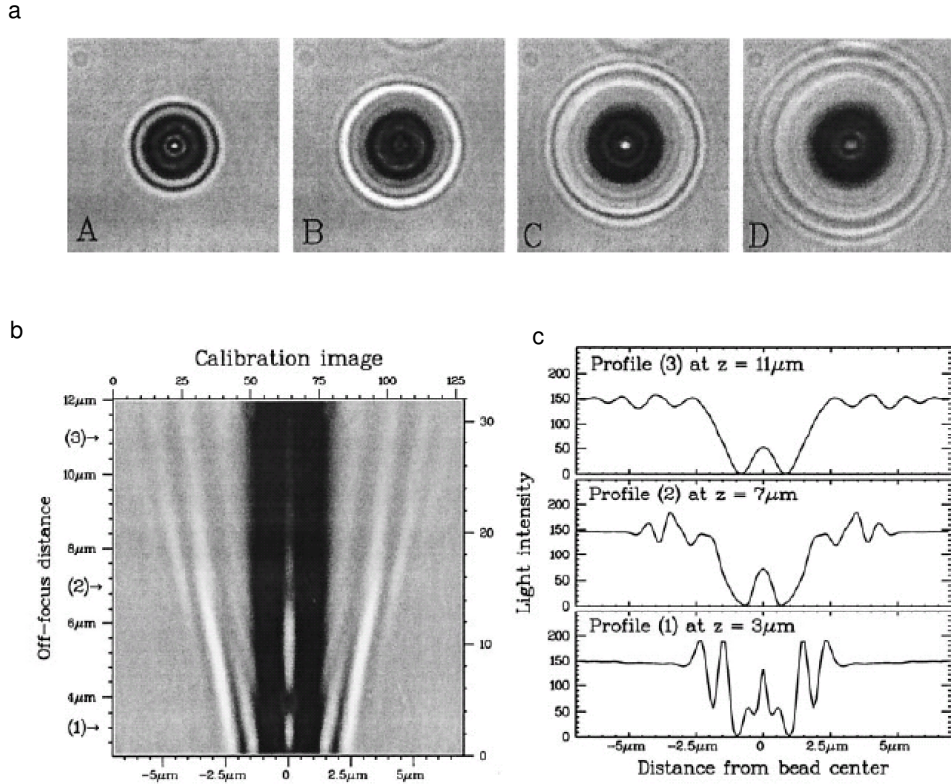

Figure 3-3

The image of the a paramagnetic bead on the capillary surface with various z positions

Figure from ref[2]

3.4 Force measurement and manipulation

With rotation of the magnets, the paramagnetic bead rotates synchronously in a step-locked register manner, which introduces super-helical turns into the torsionally constrained DNA.

The magnitude of the magnetic force applied on the DNA can be adjusted by moving the magnets along z-axis. For the DNA in the experimental setup, the magnitude of the magnetic force applied on the DNA can be monitored by Brownian motion of the paramagnetic beads. That follows the relation:

$$m \frac{d^2 x(t)}{dt^2} = -6\pi\eta R \frac{dx(t)}{dt} - k_x x(t) + f_a(t) \quad (\text{equation 3.1})$$

Here, the R is radius of the bead and η is the friction coefficient. $-6\pi\eta R \frac{dx(t)}{dt}$ is the friction force in the system. $-k_x$ is the spring constant for the restoring force of the DNA molecule which tethers the bead. The random force can be characterized as

$$\langle \vec{f}(t)_a \rangle = 0 \quad \text{and} \quad \langle \vec{f}(t)_a \vec{f}(t')_a \rangle = 4k_B T (6\pi\eta R) \delta(t - t') \quad (\text{equation 3.2})$$

The k_B is Boltzmann constant. The Fourier transform of $X(t)$ and $f_a(t)$ are:

$$X(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} x(t) \exp(-i\omega t) dt \quad (\text{equation 3.3})$$

$$F(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f_a(t) \exp(-i\omega t) dt \quad (\text{equation 3.4})$$

Then one can obtain:

$$X(\omega) = \frac{F(\omega)}{-m\omega^2 + 6\pi\eta R\omega + k_x} \quad (\text{equation 3.5})$$

However, in the system, $m \approx 10^{-15} \text{ kg}$, $\eta = 10^{-3}$, $k_x = 10^{-9} \text{ N/m}$ and $R = 10^{-6} \text{ m}$, the

term $\frac{6\pi\eta R}{m}$ is close to $\approx 3 \times 10^7 \text{ Hz}$. It can not be observed by the CCD camera

which collects images at a pace of 33 Hz in the experiment setup. Thus, the moving

equation of the bead can be rewritten as:

$$-6\pi\eta R \frac{dx(t)}{dt} - k_x x(t) + f_a(t) = 0 \quad (\text{equation 3.6})$$

The square of $X(t)$ in the ω space obtained from the equation above is

$$X^2(\omega) = \frac{F(\omega)}{k_x^2 \left(\left(\frac{\omega}{\omega_c} \right)^2 + 1 \right)} = \frac{2/\pi k_B T \cdot 6\pi R \eta}{k_x^2} \frac{1}{\left(\frac{\omega}{\omega_c} \right)^2 + 1} \quad (\text{equation 3.7})$$

Here ω_c is cut off frequency and $\omega_c = k_x / 6\pi\eta R$.

$$\langle \delta x^2 \rangle = \int_0^\omega X^2(\omega) d\omega = \frac{2/\pi k_B T \cdot 6\pi R \eta}{k_x^2} \frac{\omega_c}{2} = \frac{k_B T}{k_x} \quad (\text{equation 3.8})$$

From equipartition theory: $\frac{1}{2} k_x \delta x^2 = k_B T$ and $F/l = k_x$

Then the force due to the Brownian collision is $F = \frac{2k_B T}{\langle \delta x^2 \rangle} l$ (equation 3.9)

Therefore, the magnitude of the magnetic force can be determined by a measurement of $\langle \delta x^2 \rangle$ - the fluctuation of the paramagnetic bead and l - the tether length of the DNA molecule (**Figure 3-4**).

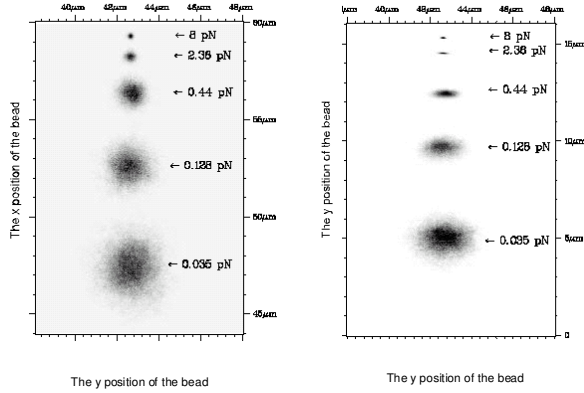

Figure 3-4

Right plane: The bead motion in microscope vertical plane y,z

Figure from ref [11].

3.5 Determination of DNA extension and force

The distance between the paramagnetic bead and the surface of a capillary in the z-axis is defined as the extension of the DNA molecule- l_{obs} (Figure 3-1). The l_{obs} here is equal to the l listed (equation 3.9) above. The extension of the DNA molecule, l_{obs} , can be obtained in real time by determination of the z position of the paramagnetic bead and a reference bead on the surface of the capillary.

The moving amplitude of the paramagnetic bead- $\langle \delta x^2 \rangle$ is obtained by taking the Fourier transform of $X(t)^2 - X(\omega)^2$ and, after removing first few modes

of $X(\omega)^2$, integrating equation 3.8. Then the magnitude of the force is determined by equation 3.9 (Figure 3-5).

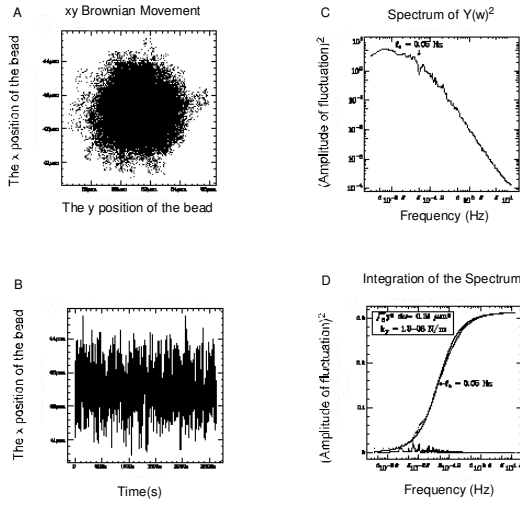

Figure 3-5

The time variance of z position of the paramagnetic bead processed with FFT

(A) The raw Brownian motion in the microscope's focal place

(B) The position of the bead along Y axis as function of time

(C) Taking the Fourier transform of the bead's position - $Y(t)$ gives $Y(\omega)^2$ as function of ω . $\omega = 2\pi f$ and the cutoff frequency: $f_c = \omega_c / 2\pi$. The amplitude of cutoff frequency below $f_c = 0.05\text{Hz}$ is constant. But the amplitude of cutoff frequency above $f_c = 0.05\text{Hz}$ drops off as $1/f^2$.

(D) Integrating of spectrum gives Lorentzian with $\langle y^2 \rangle = 0.31\mu\text{m}^2$

Figure from ref [11].

Therefore, the relationship of l_{obs} and stretching force or the degree of supercoiling of a DNA molecule can be obtained, since we can control the two parameters- the magnitude of stretching force and the degree of supercoiling of the

DNA. At a proper buffer condition and temperature, like 10 mM phosphate buffer and 25°C, we can determine the relationship of stretching force and l_{obs} of the DNA molecule.

3.6 Stretching of torsionally free DNA

For the torsionally free DNA, the force and extension curve can be categorized into three regimes of elasticity: entropy regime, enthalpy regime, regime of the transition from B-form into S-form. The low force regime is of the order of 0.1 pN ($F \approx k_B T / \zeta$), where ζ is the persistence length of a DNA molecule. In this regime, the configurational entropy of the DNA molecule is reduced by stretching; thus, it is also called the entropy regime [3]. If the force increases to the order of 10~70pN, the DNA molecule enters into another regime called enthalpy regime. In this regime, the double strand-helix of DNA is deformed. The relationship of stretching force and extension can be described as $F = EA(\frac{l-l_0}{l_0})$ [4-6]. Here, E is Young's modulus and A is the cross-sectional area of the DNA molecule. When the force arrives at 70pN, the DNA can transform from B-form into S-form (stretching form). A DNA in S-form has a 70% longer length than its crystallographic length in B-form [4]. The Worm-Like Chain model can describe the stretching behavior of DNA

below 10 pN: $F = \frac{k_B T}{\xi} \left[\frac{1}{4(1 - l/l_0)^2} - \frac{1}{4} + \frac{l}{l_0} + \sum_{i=2}^{i=7} a_i \left(\frac{l}{l_0} \right)^i \right]$ [7].

(Figure 3-6)

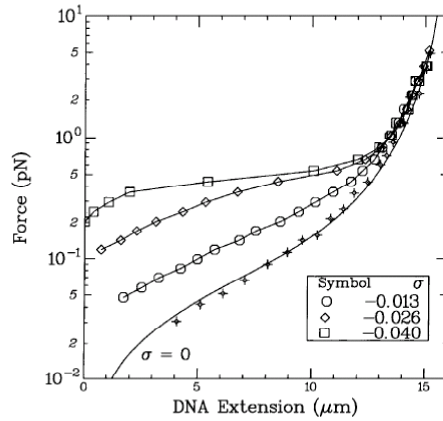

Figure 3-6

The Force vs. the DNA extension at various σ , ($\sigma = \frac{n}{Lk_0}$)

Force vs. DNA extension curves for a DNA at various σ at 10mBP buffer. $\sigma=0$ can fit into WLC model.

Figure from ref [8].

3.6.1 Stretching of supercoiled DNA

Under a fixed stretching force at which the Worm-Like Chain model can

describe the system well, l_{obs} can vary with the degree of supercoiling of the DNA

($\sigma = \frac{n}{Lk_0}$, Lk_0 is the number of turns in the relaxed DNA molecule, is determined by dividing the total base pairs of the molecule by the relaxed bp/turn which is 10.4 in B form DNA usually.). For a double-stranded DNA molecule under low force (ie. $F = 0.2 \text{ pN}$), it follows a topological relation: $Lk = Tw + Wr$. Lk is the linking number and equal to the sum of the supercoiling number (Wr , writhe number) and the twist number (Tw). A torsionally constrained DNA molecule has invariant Lk . Therefore, when rotation of the paramagnetic bead introduces superhelical turns into the torsionally constrained DNA molecule, the supercoiling number of the DNA molecule has to change and compensate the change in twist of the DNA molecule (Figure 3-7).

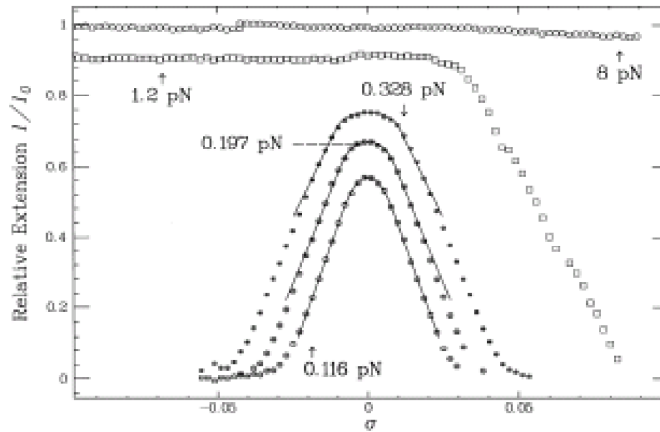

Figure 3-7

The extension of DNA vs. σ at various stretching forces

At forces below 0.328 pN, the curves are symmetric with $\sigma \rightarrow -\sigma$. At a force around 1 pN, the extension of DNA does not change as $\sigma < 0$. When the force is 8 pN, the extension of DNA does not change with σ .

Figure from ref [9].

At intermediary force ($F=1$ pN), the double stranded DNA stops formation of supercoils when underwound, instead the double stranded DNA starts to denature.

The DNA molecule, when overwound, still forms supercoils and follows the topological relationship - $\Delta Lk = \Delta Tw + \Delta Wr$ (Figure 3-7). At high force ($F=8$ pN), unwinding or overwinding of the DNA causes denaturation of the DNA molecule (Figure 3-7).

At low force, at the beginning of the twisting of the DNA, the torque applied on the DNA increases linearly with twist angle: $\Gamma = k_B T \frac{C}{l_0} \Omega$. Here, the Ω is twist angle. The $C \cdot k_B T$ is twist stiffness of the DNA molecule at a force F which

stretches the DNA molecule to l_0 . After a number of superhelical turns are introduced into the DNA molecule, the torque stops increase and becomes saturated. The DNA begins to bend and forms a loop with radius R. The torque can be described as $\Gamma = \sqrt{2BF}$ since in this regime the torque is constant. Here, B is bending stiffness constant of the DNA molecule and F is the force applied on the DNA molecule. Also, the extension of the DNA varies linearly with the number of superhelical turns which have been introduced into the DNA. It is suited to use the model at low force. At high force or intermediary force regime, the force destroys the plectonemics – tertiary structure of the DNA.

Because the DNA molecule with different degrees of supercoiling corresponds to a particular l_{obs} when the DNA is in a regime of low force ($F=0.1\text{pN}$), the calibration can be made by introducing various numbers of superhelical turns into the DNA molecule and determining each corresponding l_{obs} .

The calibration curve may cover a range of superhelical turns. There is a constant torque regime, in which the variation of l_{obs} linearly corresponds to the number of superhelical turns and the torque is constant. At 10 mM phosphate buffer and 25°C , in this regime, a change of one superhelical turn can cause a change of

$56 \pm 5 \text{ nm}$ in l_{obs} [10] (Figure 3-8). This kind of property can help the study of DNA melting by enzymes. For instance, with the experiment set up as mentioned above, for a negatively supercoiled DNA molecule with a promoter, approximately one turn of unwinding can be introduced by promoter DNA melting with RNAP, which causes a decrease in Tw . In order to compensate the loss in Tw of the DNA, the supercoiling number of the DNA molecule must increase. For a negative supercoiled DNA molecule, the increase in supercoiling number can increase the extension of the DNA (Figure 3-9). Thus, from the change of l_{obs} , we can evaluate how many turns of double stranded DNA (or DNA base pairs) have been melted. Based on the experiment construction, with 2kb DNA, the spatial resolution can be achieved at 1 bp and temporal resolution can reach 1 second.

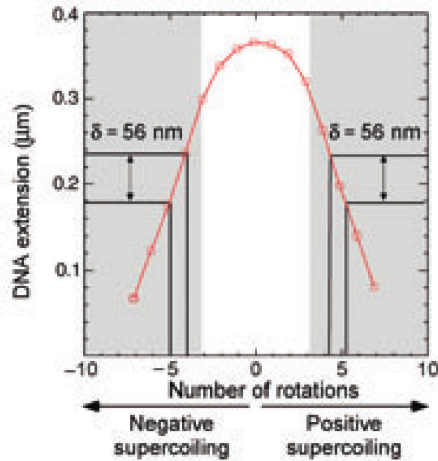

Figure 3-8

Calibration of the DNA extension vs. superhelical turns

At constant torque regime, the change of extension per-superhelical turn is 56.5 nm Figure from ref [1].

Chapter 4

Detection of initial transcription by single-molecule DNA nanomanipulation

4.1 Background and Objectives

Transcription starts when RNAP binds to a promoter and forms a closed complex. An open complex state follows the closed complex state, in which RNAP unwinds a double stranded promoter DNA into two single stranded DNAs. The previous study on promoter unwinding has demonstrated the capability of nanomanipulation technique to determine lifetime and frequency of the open complex unwinding events occurring on *lacCONS* and *rrnBP1* promoter [1].

In this object, we used a similar approach to study initial transcription on the N25_{anti DSR} promoter. Upon addition of a subset of NTPs, RNAP starts abortive initiation on the N25_{anti DSR} promoter. Different subsets of NTPs determine the different lengths of the nascent RNA. However, if the supply of subsets of NTPs is more complete, it is supposed that RNAP can make longer nascent RNA or go

through more nucleotide addition steps. Thus, when provided a more complete subset of NTPs, the lifetime of the abortive initiation state will be longer. To test this hypothesis, we determine the lifetime of the abortive initiation state with different subsets of NTPs and various concentrations of a single nucleotide.

4.2 Experimental design and methods

In the experimental setup, the 2kb long DNA fragments was used. Each DNA molecule tethers a paramagnetic bead at the end. The DNA fragment contains a promoter, a transcribed region with or without a terminator. RNAP binds to the promoter and starts RNA synthesis on the transcribed region. RNAP melts the double stranded DNA and forms a transcription bubble near the transcription start site. Since the size of the transcription bubble affect the T_w of the tethering DNA in the low force regime, in order to compensate the change in T_w , the $|Wr|$ of the DNA molecule must change as well. Thus, the l_{obs} of the DNA molecule must decrease if the $|Wr|$ increases or decrease. The melting of a couple of base pairs of the tethering DNA can result in a change in l_{obs} on the order tens of nanometers in the constant torque regime. The number of melted base pairs of the tethering DNA reflects the size of the transcription bubble. Thus, during transcription, each l_{obs} represents a

different transcription stage having a specific size of the transcription bubble. In the following chapters, we used the same experimental setup to study transcription with different DNA templates.

4.2.1 Construct of N25 promoter DNA templates

Here, we used the DNA construct N25 -100 -tr2. The N25 -100 -tr2 has a N25 promoter, a 100 bp transcribed region and *tR2* terminator (Figure 4-1). We choose the N25 promoter as this promoter was characterized in the bulk measurement [2].

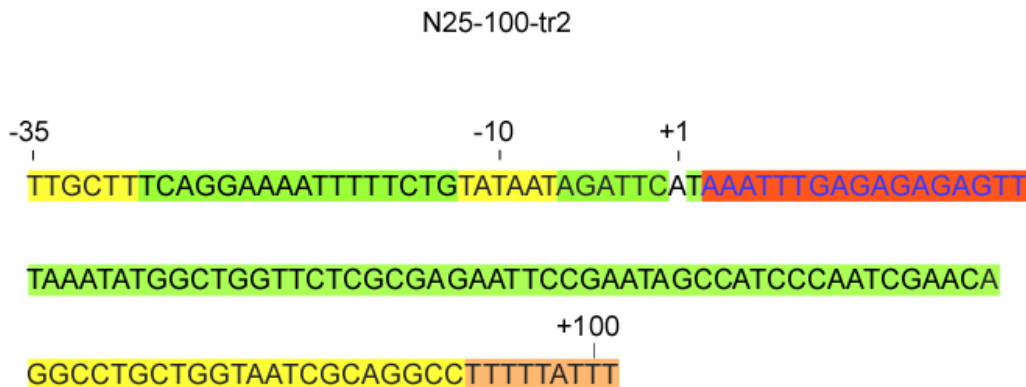

Figure 4-1

The constructs of the N25-100-tr2 (Top strand)

The promoter element -10 and -35 are in yellow. The ITS is in the red. The inverse sequence of *tR2* terminator is in yellow and the poly U corresponding sequence is in orange. (Top strand)

4.2.3 Determine abortive initiation kinetics with the subset of NTPs

By providing subsets of NTPs-ATP or ATP/UTP to the system with the N25 -100 -tr2 construct, RNAP can start initiation; and the lifetime of the ITC with each subset of NTPs can be determined. This information may help in building up a model of the transcription abortive initiation kinetics. We also used a subset of NTPs with low concentration of UTP (2 μ M) and high concentration of ATP (500 μ M) in determining the change of DNA extension (Δl_{obs}) during abortive initiation on the N25 -100-tr2 construct.

4.2.4 Basic experiment setup

The DNA construct is incorporated into a 2kb DNA, a fragment of Rpo C gene of *Thermus thermophilus* from 2050 to 4050 bp. The two ends of the 2kb DNA are ligated with biotinylated 1kb DNA and digoxigenin labeled 1 kb DNA, respectively (Figure 4-2). In each of the following experiments, we use the same method to construct tethering DNA.

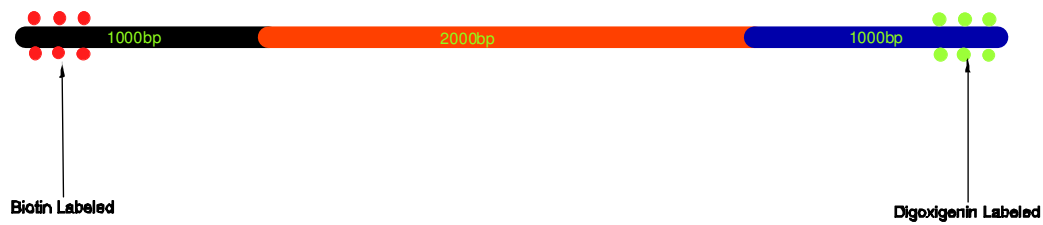

Figure 4-2

The design for the tethering DNA

The two ends of the 2kb DNA were ligated with biotinylated 1kb DNA and digoxigenin labeled 1 kb DNA.

The whole construct is used as a tethering DNA in the nanomanipulation experiment as follows (Figure 4-3).

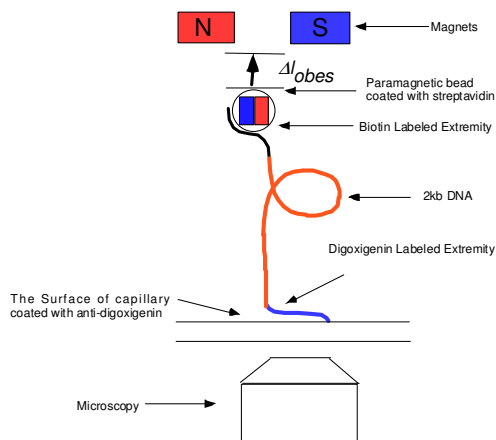

Figure 4-3

The DNA construct in Figure 4-2 used in the nanomanipulation experiment

The DNA tethers the paramagnetic bead through the binding of biotin and streptavidin, and it is anchored on the glass surface by interaction of digoxigenin and anti-digoxigenin.

4.2.5 Data analysis

The lifetime of ITC on N25 promoter was obtained by determining the time window between the two transitions of l_{obs} which correspond to the formation of ITC and collapse of ITC. Each lifetime of ITC on the N25 promoter corresponding to a particular subset of NTPs was obtained from the average of data for each particular subset of NTPs.

4.3 Results

The table 4.1 shows the lifetime of abortive initiation state of RNAP on N25 promoter with the various subsets of NTPs.

nucleotide	Non	ATP	ATP/UTP
Lifetime (second)	38±4	48±3	250±30

Table 4-1

The lifetime of ITC on the N25 promoter with various sets of nucleotides

With low concentration of UTP (2 μ M) and high concentration of ATP (500 μ M) in the system, the ITC on the N25 promoter changes the DNA extension (l_{obs}) with time.

The time trace of DNA extension has a tooth-like pattern (Figure 4-5). The number of nucleotides incorporated into the nascent RNA is proportional to the change in DNA extension (Δl_{obs}). As RNAP synthesized RNA after the first two nucleotides, the bubble began to extend downstream of the N25 promoter, according to the model proposed by Hsu [2]. The largest size nascent RNA with a supply of ATP/UTP in the system with the N25 promoter is 8 nt. At the beginning of initiation, the size of ITC bubble is equal to the size of open complex bubble. The RNAP keeps incorporating nucleotides into the RNA until the size of the DNA: RNA hybrid reached a length of 8 bp. Thus, with a supply of ATP/UTP to the system with the N25 promoter, the change in DNA extension (Δl_{obs}) caused by formation of the ITC is larger than the one corresponding to an open complex (Figure 4-4). In the presence of low concentration of UTP (2 μ M) and high concentration of ATP (500 μ M), the DNA extension (l_{obs}) changes with time. Because UTP was limited relative to ATP, we were able to observe the transitions of sub-states of abortive initiation (Figure 4-5).

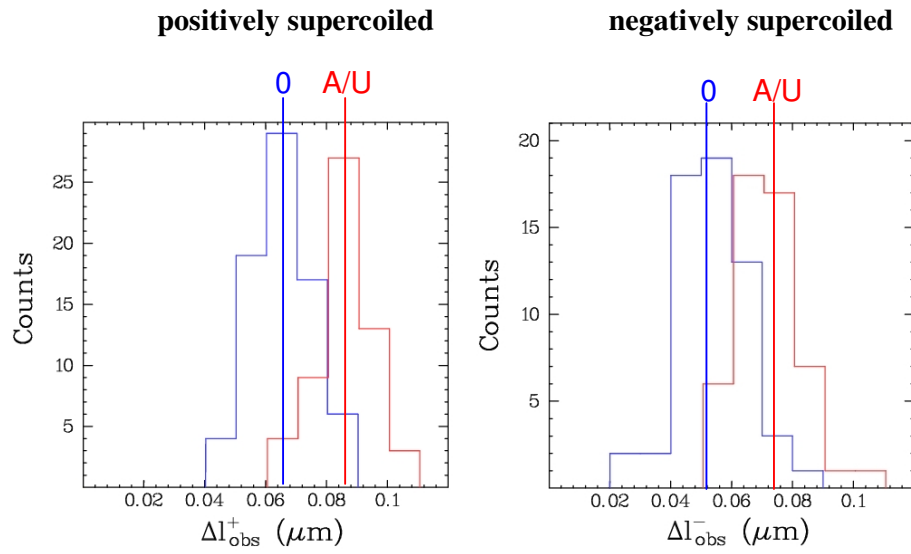

Figure 4-4 The transition amplitude histograms for RPo (0 NTPs) and RPitc, ≤ 8 (ATP+UTP) at the N25 promoter; Δl_{obs}^+ , transition amplitude with positively supercoiled DNA; Δl_{obs}^- , transition amplitude with negatively supercoiled DNA.

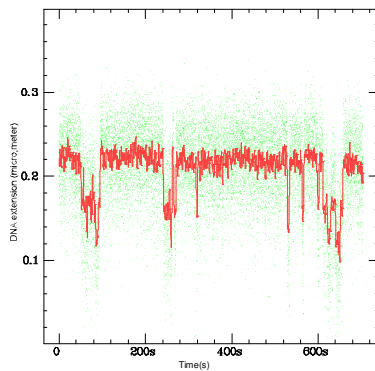

Figure 4-5
The time trace of DNA extension in abortive initiation on the N25 promoter with ATP (500 μM) and UTP (2 μM)

4.4 Conclusions

The lifetime of ITC increases when it is provided with the first two initial nucleotides. This indicates that the abortive initiation state is more stable in the

presence of the first two initial nucleotides. The more NTPs are added to the system, the longer is the nascent RNA transcripts. This result also implied that the rate limiting step of the promoter escape is at abortive initiation RNA synthesis rather than at the stage of promoter rewinding because the lifetime of ITC becomes longer upon adding a more complete subsets of NTPs.

Figure 4-5 represents the DNA extension during abortive initiation, which reflects the changes in transcription bubble size during abortive initiation. It has been easily observed that the ITC with a 8 nt DNA:RNA hybrid caused a larger change in DNA extension (l_{obs}) than of open complex (Figure 4-4). Since the different transcription bubble size can represent the length of nascent RNA products, from Figure 4-4, it can be interpreted as the change in length of nascent RNA during abortive initiation. RNAP repeated cycles of the RNA synthesis and release of the nascent RNA product in different lengths. These cycles were repeated until the RNAP dissociated from the promoter.

Chapter 5

Detection of promoter escape by single-molecule DNA nanomanipulation

5.1 Background and Objectives

Promoter escape is the last step of transcription initiation, following the abortive synthesis of nascent RNA. As RNAP escapes from a promoter, it begins elongation along a template DNA molecule. We have discussed the abortive synthesis of nascent RNA on the N25 promoter with a supply of NTPs subsets in the previous chapter. RNAP is in a cycle of synthesizing and aborting nascent RNA, restarting the synthesis of nascent RNA. Without a full set of NTPs, the RNAP can not escape from a promoter and stays in the cycle of synthesizing and aborting RNA until the RNAP dissociates from the promoter. Therefore, we used a full set of NTPs to determine promoter escape on the N25 promoter.

5.2 Experimental design and methods

With a full set of NTPs, RNAP can start abortive initiation on the N25 DNA

templates and escape from the promoter. Through the changes of the DNA extension, the ITC can be easily identified and distinguished from the open complex and the TEC.

We use a DNA template N25-100-tr2⁻ (Figure 5-1). The DNA template has the N25 promoter, a 100 bp transcribed region and a modified *tR2* terminator. The terminator on the N25-100-tr2⁻ has been modified by a change of *T* ↔ *G* on the T-tract sequence of the *tR2* terminator, which can abort the transcription termination on this modified terminator.

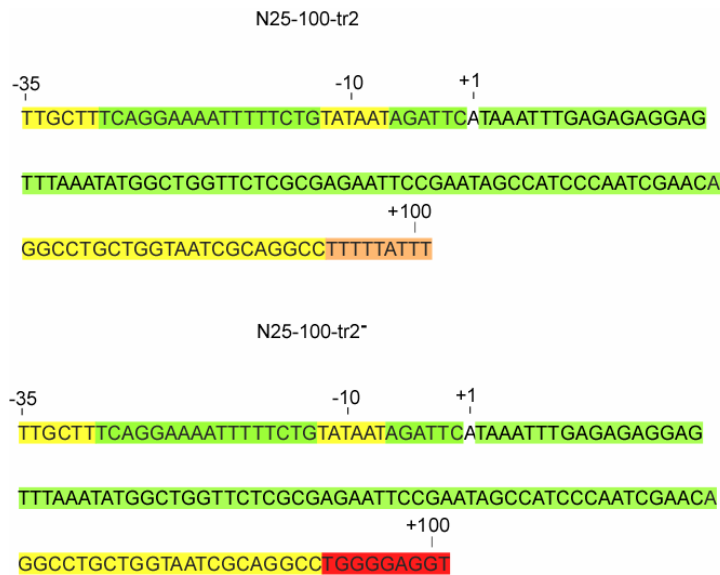

Figure 5-1

The N25-100-tr2 and N25-100-tr2⁻ DNA templates (top strand): An invert repeat sequence (in yellow) is next to the ploy G region (red) or the poly T region (in orange).

5.3 Results

In a transcription assay experiment, with a full set of NTPs, most RNAP read through the *tR2*⁻ terminator while transcribing on the N25-100-tr2⁻ DNA template (Figure 5-2).

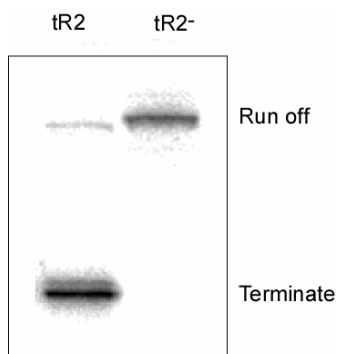

Figure 5-2

In the transcription assay experiment, most RNAP read through the *tR2*⁻ terminator while some RNAP terminated at *tR2* terminator.

With a full set of NTPs, after abortive initiation, the RNAP escaped from the promoter and entered elongation (Figure 5-3). Base on the observation in chapter4 (figure 4-x), it is clear that the ITC corresponds to a larger size of DNA extension than an open complex in N25 promoter. When RNAP entered into the elongation state, the DNA extension reduced from one corresponding to the ITC. The RNAP continues elongation and reads through the N25-100-tr2⁻.

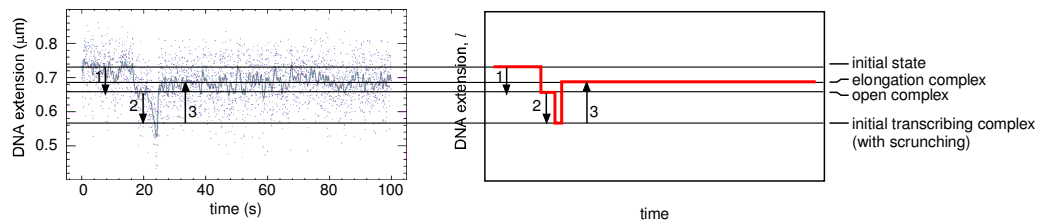

Figure 5-3

The time trace of a transcription event on the N25-100-tr2' construct: the transition 1 corresponds to formation of open complex, transition 2 corresponds to formation of ITC, transition 3 is formation of TEC.

5.4 Conclusions

It has also been found in footprint experiments that the RNAP upstream promoter contacts are fixed during abortive initiation, but the active center of RNAP can move relative to the template DNA [1]. In order to explain this observation, three models have been proposed for abortive initiation: the inchworm model, the transient excursion model and the scrunching model. The inchworm model and the transient excursion model predict that the size of the ITC bubble is fixed during transcription and is almost equal to the size of the open complex bubble. However, the scrunching model proposes an increase of bubble size when RNAP is in the abortive initiation stage. Through the observation of the change in the DNA extension, it shows that open complex bubble extends to the ITC bubble during abortive initiation (Figure 5-3). Therefore, we conclude that abortive initiation occurs via the scrunching mechanism in *Escherichia coli* RNAP.

5.4.1 Initiation-elongation transition is within the time resolution of nanomanipulation

One can assume that the more stable an ITC is, the less abortive RNA transcripts are made. From the abortive transcript probability profile, most transcription abortive events occur at 8 nt for N25 promoter [2]. This means that RNAP confronts a rate determining step for promoter escape when the length of nascent RNA reaches 8 nt. With a supply of 100 μ M NTPs, this rate determining event of promoter escape must occur within the time resolution of nanomanipulation. If this was not the case, we would be able to observe a DNA extension- I_{obs} which corresponds to a transcription bubble with a size of 8 nt. Because the rate determining step of promoter escape on the N25 promoter occurs at 8nt from transcription start site, when the ITC reaches the rate determining step, the ITC has 8 nt DNA:RNA hybrid. Then one is able to observe a transcription bubble with a size of 8nt on the N25 promoter during initiation-elongation transition like the transcription bubble in Figure 4-5. It is clear, in Figure 5-3, that there is no other sub-state transition during abortive initiation being observed like those in Figure 4-5. Therefore, the time resolution of nanomanipulation does not allow us to determine the time for the N25 promoter escape with a supply of 100 μ M NTPs.

Chapter 6

Detection of elongation and termination by single-molecule DNA nanomanipulation

6.1 Background and Objectives

In the previous chapter, we showed by nanomanipulation that we could observe that RNAP escaped from a promoter and entered into elongation. Following elongation, termination occurs during a normal transcription. During transcription termination, RNAP rewinds the melted DNA and releases itself from the template DNA. Each transcription stage involves different sizes of transcription bubbles. Each transcription bubble corresponds to a change in the DNA extension (Δl_{obs}), so we can assign each transcription stage to each corresponding l_{obs} . Therefore, by observing the change of Δl_{obs} with time, we were able to determine the kinetics of elongation and termination events.

6.2 Experimental design and methods

In the last chapter, we used a DNA template- N25-100-tr2⁻ which has a modified *tR2* terminator, and most RNAPs read through the terminator without terminating RNA synthesis. In order to detect the termination events, we construct a DNA template N25-100-tr2, which has N25 promoter, a 100 bp transcribed region and a *tR2* terminator (Figure 6-1). When RNAP transcribes on the N25-100-tr2 and reaches the terminator, transcription termination should occur.

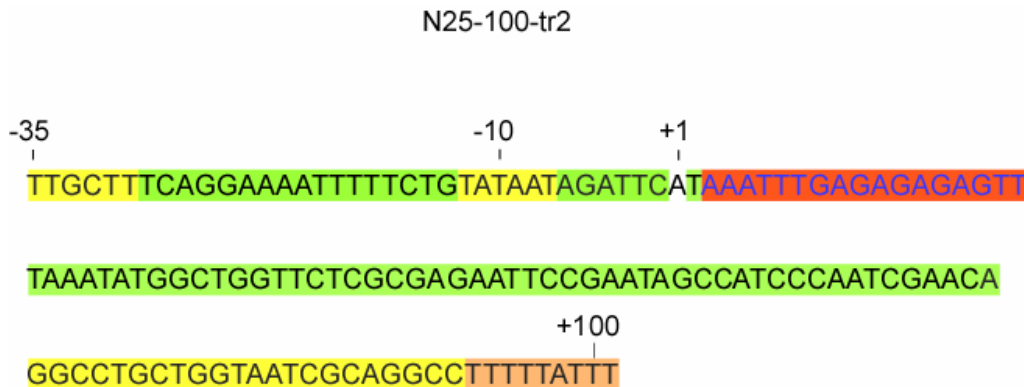

Figure 6-1

N25-100-tr2 DNA templates (top strand): The promoter element -10 and -35 are in yellow. The inverse sequence of *tR2* terminator is in yellow and the poly U corresponded sequence is in orange. The N25-100-tr2 DNA template has a terminator (in orange).

6.3 Results

The time trace for l_{obs} during the transcription carried out on the DNA template

N25-100-tr2 by the single-molecule nanomanipulation is shown in Figure 6-2. This time trace corresponds to a complete transcription event with different transcription stages. These transcription stages and their corresponding Δl_{obs} have been discussed in the previous chapters. We can assign transition 1 as the formation of the open complex, transition 2 as the formation of the initial transcribing complex, and transition 3 as the formation of the elongation complex.

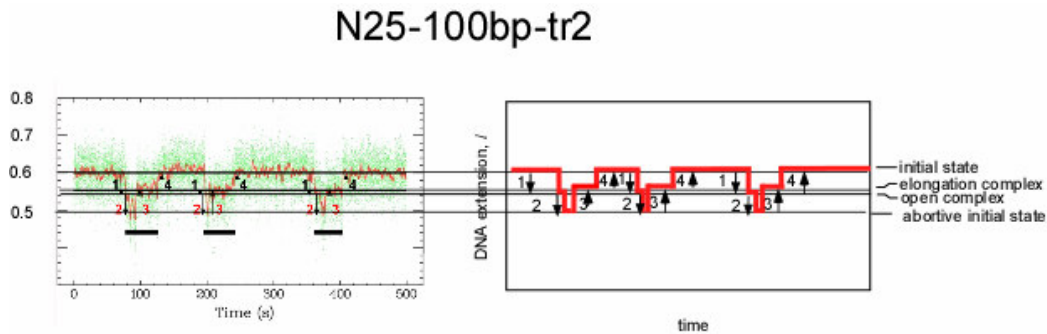

Figure 6-2

The time trace of RNAP transcribing on the N25-100-tr2 DNA template: the transition 1 corresponds to formation of open complex, transition 2 corresponds to formation of ITC, transition 3 is formation of TEC and transition 4 corresponds to termination. The time frame between transition 2 and transition 3 is the abortive initiation state, and the elongation state is between transition 3 and transition 4. Therefore transition 1 to transition 4 is a complete transcription event.

6.4 Conclusions

In order to verify that transition 4 of l_{obs} corresponds to a termination event in Figure 6-2, we compare the time traces of l_{obs} for the two DNA templates. It is clear

that for N25-100-tr2⁻ which has the modified tr2⁻ terminator, the time trace of the l_{obs} after transition 3 could not return to the initial state. From the result of transcription assay experiment, it was observed that most RNAP read through the modified tr2⁻ terminator and continued elongation (Figure 5-3). Thus, the time trace of the l_{obs} after transition 3 corresponds to the elongation state. On the contrary, for the N25-100-tr2 which has the *tR2* terminator, in the transcription assay experiment, the RNAP terminated the synthesis of RNA and released the RNA product when RNAP arrived at the terminator. The trace of l_{obs} for RNAP transcribing on the N25-100-tr2 returns to the initial state. When this occurs, this implies that RNAP completed a transcription cycle on the DNA template and rewound the melted DNA template. Therefore, the transition 4 in Figure 6-2 corresponds to a termination event. The time between transition 3 and transition 4 is the elongation time.

Chapter 7

Determination of kinetics of elongation and termination

7.1 Background and Objectives

In the previous chapters, we have detected transcription elongation and terminator rewinding. In this chapter, I will discuss how to determine the kinetics of these events. We also used single-molecule nanomanipulation to study termination kinetics of DNA templates with various transcribed region lengths.

T is the time for transcription during elongation and terminator rewinding between transition 3 and transition 4 in Figure 6-2. In order to determine the kinetics, we have to know how long an elongation stage takes. Under the assumption that the elongation time is proportional to the transcribed region length, the distribution of T for various transcribed region lengths is Gaussian. For a particular DNA template, T can be expressed as:

$$T = t_{\text{elongation}} + t_{\text{terminator rewinding}} + t_{\text{unscrunching}} \quad \text{or}$$

$$T = \frac{l}{v_{\text{elongation}}} + \frac{1}{v_{\text{terminator rewinding}}} + \frac{1}{v_{\text{unscrunching}}}$$

where $t_{\text{elongation}}$, $t_{\text{terminator rewinding}}$ and $t_{\text{unscrunching}}$ are the times corresponding to elongation, terminator rewinding, and promoter escape, respectively. l is the length of the transcribed region. $v_{\text{elongation}}$, $v_{\text{terminator rewinding}}$ and $v_{\text{promoter rewinding}}$ are the velocities for elongation, terminator rewinding, and promoter escape, respectively. In Chapter 5.4.1, it has been shown that $v_{\text{promoter rewinding}}$ here is much larger than the $v_{\text{elongation}}$ and $v_{\text{terminator rewinding}}$. Thus, the promoter rewinding event can occur within the time resolution of the nanomanipulation. And in Chapter 8.3.3, it will show that the different promoters will not affect the elongation plus terminator rewinding time, which implies the time of promoter rewinding is very short comparing to the elongation time plus terminator rewinding time. Therefore, $t_{\text{promoter rewinding}}$ can be ignored in the measurement. By increasing the length of the transcribed region l , it will prolong the time for elongation $t_{\text{elongation}}$. We are trying to demonstrate the relationship between the transcribed region length of the DNA template and the time T , as described by $T = \frac{l}{v_{\text{elongation}}} + \frac{1}{v_{\text{terminator rewinding}}} + \frac{1}{v_{\text{promoter rewinding}}}$. (equation 7-1)

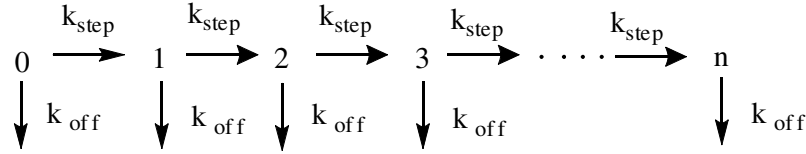

To prove this relationship, we constructed DNA templates with the N25 promoter, *tR2* terminator, and various transcribed region lengths from 160 bp-340 bp

(Figure 7-1). The transcribed regions of the DNA templates had identical repeat sequence, but various repeat numbers. Since each template had different numbers of tandem repeat sequences in the transcribed region, $t_{elongation}$ should increase proportionately to the transcribe region length.

We measure T and calculate the average of T for RNAP transcription over various transcribed region lengths of the DNA templates shown in table 7-1. Figure 7-2 shows that RNAP elongated on a template DNA at a heterogeneous velocity, which agrees with the study in [1]. However, the width of the distribution increased proportionately to the length of transcribed region (Figure 7-2). According to Eq 7-1, the $t_{terminator\ rewinding}$ for the $tR2$ terminator can be extracted by making a linear regression plot for each T over various transcribed region lengths.

7.1.1 Statistical model

Another way to study the elongation of RNAP on the DNA template can be described by the following statistical model (Scheme 7-1) [2].

Scheme 7-1

In the model, the RNAP begins translocation at 0 and moves one step forward each time and can not move back. Each step normally corresponds to the incorporation of a single nucleotide. The k_{step} is the rate constant for each step on the DNA template. Here, we assume the k_{step} is identical for each step, and that each step is statistically independent. The k_{off} is the rate constant for other reaction pathways like a transcription pausing or arrest. Then the probability of RNAP moving along the DNA template can be expressed by the equations derived as follows:

For $n=0$:

$$\frac{dP_0(t)}{dt} = -(k_{\text{step}} + k_{\text{off}}) \cdot P_0 \quad (\text{equation 7-2})$$

$$\frac{dP_0}{P_0} = -(k_{\text{step}} + k_{\text{off}})dt \quad (\text{equation 7-3})$$

Integrate equation 7-3, one can obtain:

$$P_0 = \exp[-(k_{\text{step}} + k_{\text{off}}) \cdot t] \quad (\text{equation 7-4})$$

For $n=1$:

$$\frac{dP_1(t)}{dt} = (k_{\text{step}} \cdot P_0) - (k_{\text{step}} + k_{\text{off}}) \cdot P_1 \quad (\text{equation 7-5})$$

$$\frac{dP_1(t)}{dt} + (k_{step} + k_{off}) \cdot P_1 = k_{step} \cdot P_0 \quad (\text{equation 7-6})$$

Substitute equation 7-6 with $P_0 = \exp[-(k_{step} + k_{off}) \cdot t]$ which is obtained by

integration of equation 7-3. One can have:

$$\frac{dP_1(t)}{dt} + (k_{step} + k_{off}) \cdot P_1 = k_{step} \cdot \exp[-(k_{step} + k_{off}) \cdot t] \quad (\text{equation 7-7})$$

Divide both sides of (equation 7-7) with $\exp[-(k_{step} + k_{off}) \cdot t]$

Then it gives (equation 7-8)

$$\exp[(k_{step} + k_{off}) \cdot t] \frac{dP_1(t)}{dt} + [\exp(k_{step} + k_{off}) \cdot t](k_{step} + k_{off}) \cdot P_1 = k_{step} \quad (\text{equation 7-8})$$

Again, integrate (equation 7-8)

$$\frac{d[[\exp(k_{step} + k_{off}) \cdot t] \cdot P_1(t)]}{dt} dt = k_{step} \cdot dt \quad (\text{equation 7-9})$$

One can have

$$P_1(t) = [\exp-(k_{step} + k_{off}) \cdot t] \cdot k_{step} t \quad (\text{equation 7-10})$$

By extension, one can obtain

$$P_n(t) = (k_{step} t)^n \frac{(-\exp(k_{step} + k_{off}) \cdot t)}{n!} \quad (\text{equation 7-11})$$

During elongation, the rate constant for reaction leading to a transcription pause or

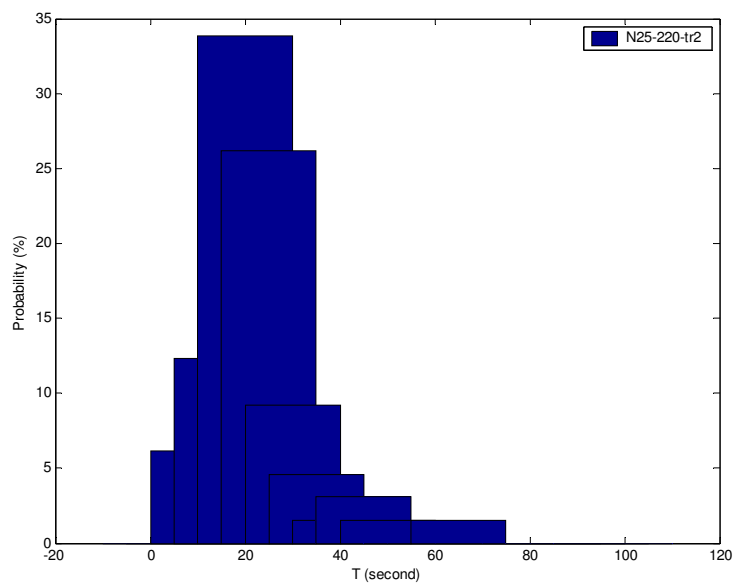

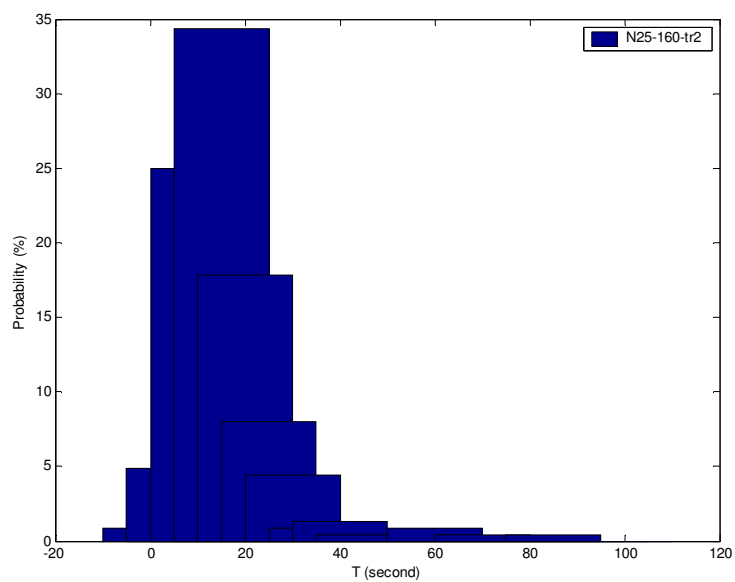

arrested state is small, k_{off} can be ignored:

$$P_n(t) = (k_{step} t)^n \frac{-\exp(k_{step} t)}{n!}$$

Thus, in this model, after transcribing for a time t , the probability of the RNAP being on the n^{th} nucleotide position of the DNA template follows a Poisson distribution.

7.2 Experimental design and methods

We prepared DNA constructs: N25-160-tr2, N25-220-tr2, N25-280-tr2, and N25-340-tr2 by increasing the number of nucleotides in the transcribed region at 60 bp increments (Figure 7-1). By carrying out transcription on these DNA templates, the termination and elongation kinetics were determined, which will be discussed in the following section.

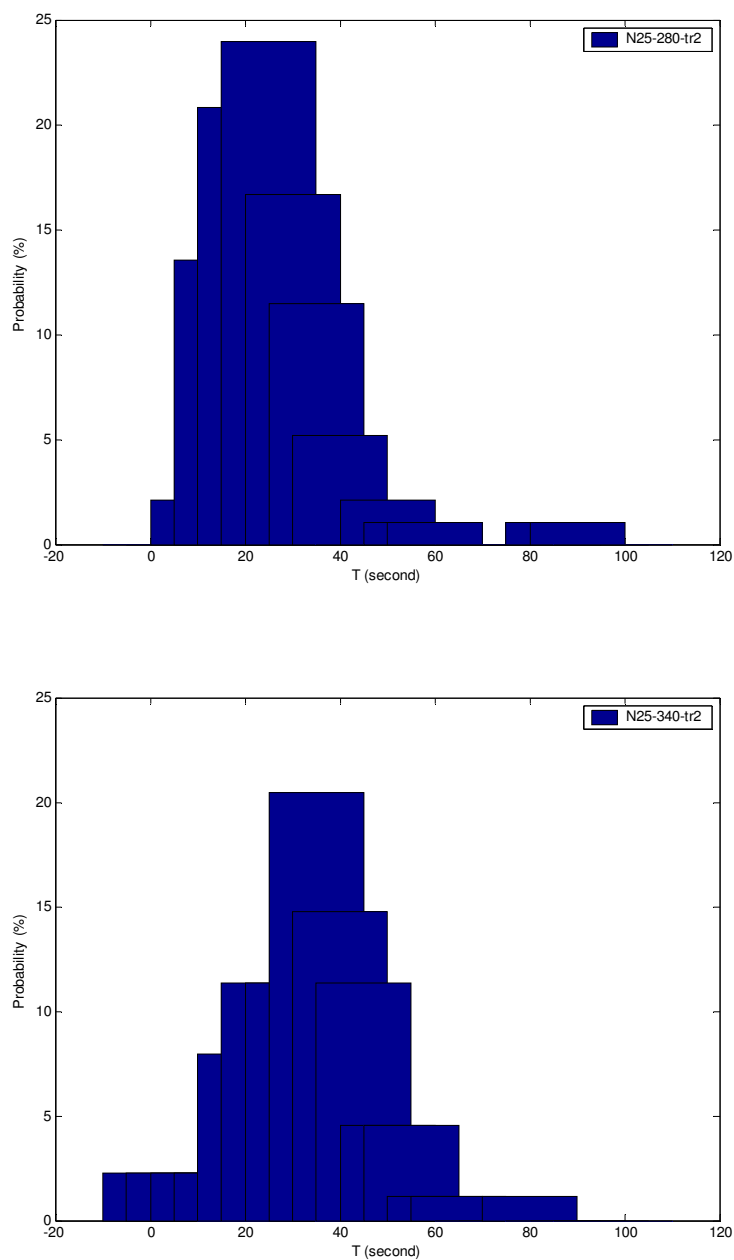

Figure 7-2

The distributions of T with each different length of transcribed region of DNA templates: the distributions were normalized by the number of data for each particular length of transcribed region of template DNA.

7.3.1 Data analysis

7.3.1.1 The analysis based on linear regression

Each data from the same transcribed region length was treated as a Gaussian distribution. After fitting the data with a Gaussian distribution, the outliers were defined as data beyond 3 times the standard deviation from mean. After removing these outliers, the average of each set of data is shown in Table 7-1 (B). Even with this adjustment, the average of data still cannot be fitted well into a linear function. In order to further reduce the deviation from a linear function, the means of the data were obtained by fitting the rest of data into a Gaussian distribution. In this Gaussian distribution fitting, each mean value corresponds to the peak of each Gaussian distribution and is shown in Table 7-1 (A). The reason for us to treat the data in the two different ways (the results are shown in Table 7-1 (A) and (B)) is that the mean values obtained from Gaussian distributions fitting are different with the average of the data for which the outliers have been removed. The mean value for each transcribed region length of DNA template was used in the linear regression, from which the t_{R2} terminator rewinding time and elongation velocity were determined

	N25-100-tr2	N25-160-tr2	N25-220-tr2	N25-280-tr2	N25-340-tr2	N25-400-tr2
A	12.5s	19.2s	26.0s	29.4s	37.0s	42.0s
B		21.4s	26.8s	32.3s	42.0s	
C		21.6s	27.2s	32.7s	42.5s	

Table 7-1 The T over various transcribed region lengths ((A) The T is the mean of the data and is obtained by fitting the data into a Gaussian distribution after removing outliers. (B) The T is the average of data after removing the outliers. (C) The T is the average of data and obtained without removing any raw data.)

T is linearly correlated with the nucleotide number of the transcribed region. From these results, the elongation velocity of RNAP on the N25-100~400-tr2 DNA templates is around 10 ± 1 bp/s , and the terminator rewinding time of $tR2$ terminator is 3.4 ± 2.9 seconds (Figure 7-3).

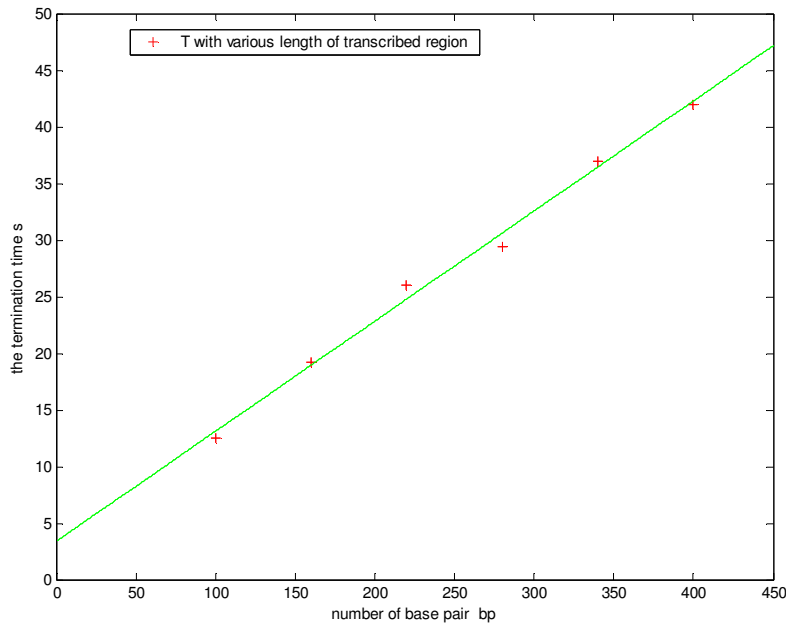

Figure 7-3

The linear regression of the data which correspond to each particular length of transcribed region of template DNA: N25-100~340-tr2.

7.3.1.2 The analysis based on Poisson Statistics

Each data set from the same transcribed region lengths was treated as a Poisson distribution. In this case, the fitting using a general linear model has a link function $-\log$. The distributions of T over different transcribed region lengths are shown in Figure 7-2. The result of fitting of General linear model with Poisson distribution is: $\log(T) = 2.48 + 0.0037 \cdot l$ or $T = e^{2.48+0.0037 \cdot l}$. Here, the l is the length of transcribed region. The elongation velocity from the fitting of the data can be expressed as $v = \frac{\partial l}{\partial T} = \frac{1}{0.0037} \cdot e^{-(0.0037 \cdot l + 2.48)}$. Thus, the elongation velocity is not

constant along the DNA template. Instead, the elongation velocity decreases with an increase in the nucleotide number of the transcribed region. In the transcribed region 160 bp ~340 bp, the velocity varies from 12.5 bp/s to 6.4 bp/s. The time for terminator unwinding is 11.94 ± 0.35 second.

7.5 Conclusions

The elongation velocity and the *tR2* terminator rewinding time determined by single-molecule nanomanipulation are 3.4 seconds and 10 bp/s, respectively, using linear regression. The elongation velocity here is close to the elongation velocity previously determined by single molecule technique [3]. The termination rewinding time measured here is lower than termination time determined from other terminators (14~8 seconds) by conventional method [4]. A possible explanation for the termination rewinding time being lower than the termination time could be the involvement of other termination processes and the other processes take a comparable order of time. A complete termination event can involve cessation of RNA synthesis, release of RNA transcript, and release of the RNAP from the DNA template. The release of the RNA transcript can correspond to the collapse of elongation bubble or DNA rewinding, which can reflect on the Δl_{obs} . If the termination time for *tR2* terminator is between 14~8 seconds, it implies the release of the RNAP from the DNA

template plays an essential role in the kinetics of termination.

Using the Poisson regression, the terminator rewinding time for $tR2$ is 11.9 seconds, which is much closer to the observed termination time for other terminators. However, the regression was based on an assumption that the kinetics of elongation is a Poisson process, such that the elongation velocity of RNAP is not constant. Instead, RNAP moves more quickly at the beginning of transcription than at the end of transcription. It might be able to explain why lower elongation velocity was obtained from most single-molecule experiments while higher elongation velocity was determined from most of conventional experiments. Because, in these single-molecules experiments, the elongation velocity was obtained by providing DNA templates with a length of a couple kb in transcribed region while in most of conventional experiments the elongation velocity was obtained by using the DNA templates with shorter transcribed region length. A Poisson process has also been observed with DNA polymerase synthesizing DNA fragments [5]. Thus, a similar model may apply to transcription as well.

Chapter 8

Determination of effects of promoter sequence on initial transcription, promoter escape, elongation, and termination

8.1 Background and Objectives

The N25 DNA construct and the N25_{antiDSR} construct are identical in the promoter recognition region but the downstream region of the N25 promoter from +3 to +20 has been replaced with $A \leftrightarrow C / G \leftrightarrow T$. RNAP's initial transcription on the N25 and the N25_{antiDSR} promoters has been well characterized by conventional experiments [1-3]. RNAP on the N25_{antiDSR} construct has a different kinetic behavior than the N25 construct during initial transcription. For instance, transcription has a lower abortive to productive ratio (APR) on the N25 promoter than on the N25_{antiDSR} promoter. The maximum size of the initial transcript for the N25 promoter is 10 nt, while it is 15 nt for the N25_{antiDSR} promoter. The abortive probability is also different between the two promoters (Figure 8-1).

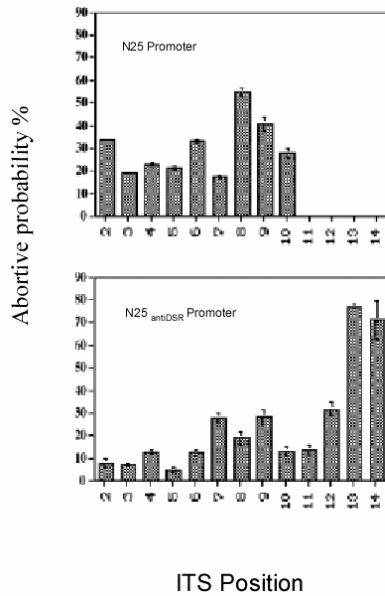

Figure 8-1

The profile of abortive probability over different ITS position for the N25 promoter and the N25_{antiDSR} promoter. Figure from ref [4].

These kinetic differences can be studied by nanomanipulation. It is also unknown whether the difference in promoters affects the kinetics of transcription elongation and termination steps. Thus, in this chapter, we investigate the kinetics of transcription with the N25 and the N25_{antiDSR} promoter.

8.2 Experimental design and methods

We used the N25-160-tr2, N25-220-tr2, N25-280-tr2 and N25-340-tr2 constructs as the DNA templates in order to characterize the transcription kinetics of RNAP on the N25 promoter. These DNA templates have identical promoters, but in the length of the transcribed region. In order to characterize the kinetics of RNAP

on the N25_{antiDSR} construct, we used N25_{antiDSR}-160-tr2 as the DNA template. The construction of N25-160~340-tr2 and N25_{antiDSR}-160-tr2 DNA template are shown in Figure 7-1 and Figure 8-2, respectively.

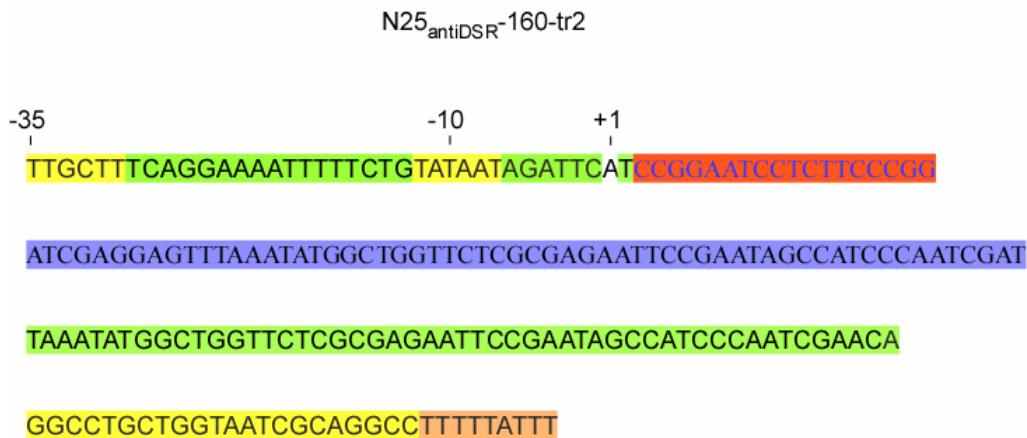

Figure 8-2

The constructs of the N25_{anti}DSR-160-tr2 (Top strand)

The promoter element -10 and -35 are in yellow. The ITS is in the red. A 60 bp (+13 to +66 in N25-100-tr2) insert is blue. The inverse sequence of *tR2* terminator is in yellow and the poly U corresponded sequence is in orange.

The kinetics of transcription can be extracted from the time trace of I_{obs} while a transcription event occurs. For instance, the lifetime of the abortive initiation state was determined by the distribution of time between transition 2 and transition 3 of the RNAP transcription time trace (Figure 6-2). The outliers in the collected data, again defined as data beyond 3 times the standard deviation, were removed before further data processing. The lifetime of initial transcription for DNA templates with the

N25 or N25_{antiDSR} promoters was obtained by fitting the remaining data with a Gaussian distribution.

The DNA extension caused by abortive initiation was obtained by adding the Δl_{obs} of transition 1 and transition 2 from the time trace (Figure 6-2). However, due to the spatial resolution or other unknown reasons, the l_{obs} did not always return to the initial level after a complete transcription event, making it difficult to precisely determine the DNA extension caused by abortive initiation. In order to have a more precise determination for the DNA extension caused by abortive initiation, the l_{obs} time trace is treated as a datum only when the difference between l_{obs} immediately before transcription initiation and immediately after termination is less than 20 nm. As before, the outliers in the collected data were defined as data beyond 3 times the standard deviation and were removed before further data processing.

8.3 Results

8.3.1 The open complex on the N25 promoter vs. the N25_{antiDSR} promoter

The result of open complex formation shows that it caused a larger DNA extension on the N25_{antiDSR}-160-tr2 construct than on the N25-160~340-tr2 constructs (Table 8-1, Figure 8-2). This could be due to the larger size of the transcription bubble on the N25_{antiDSR} promoter than on the N25 promoter. Alternatively, the N25_{antiDSR} promoter could cause larger DNA compaction in the open complex.

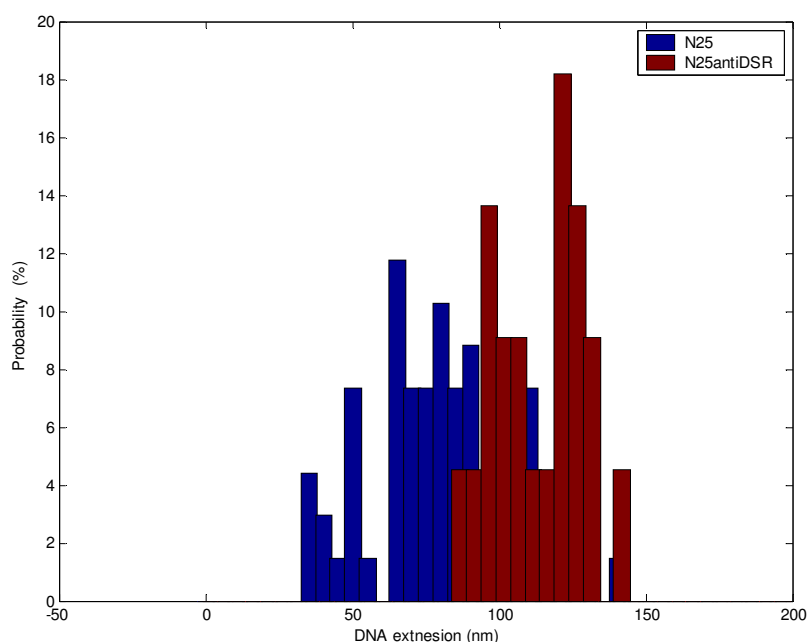

Figure 8-3

The distribution of DNA extensions caused by the formation of open complex on the N25 promoter and the N25_{antiDSR} promoter. (See Appendices A, B, C, and D)

8.3.2 Transcription initiation on the N25 promoter and the N25_{antiDSR} promoter

RNAP on the N25_{antiDSR} promoter took 6 times as long to escape from the promoter than on the N25 promoter (table 8-2). The distributions of initial transcription lifetime on the DNA templates of N25-160~340-tr2 are very similar (Figure 8-4). Figure 8-5 shows the similarity among the DNA extension distributions. Again, this indicates that the initial transcription was not affected by the DNA sequence downstream of the N25 promoter on the N25-160~340-tr2 DNA

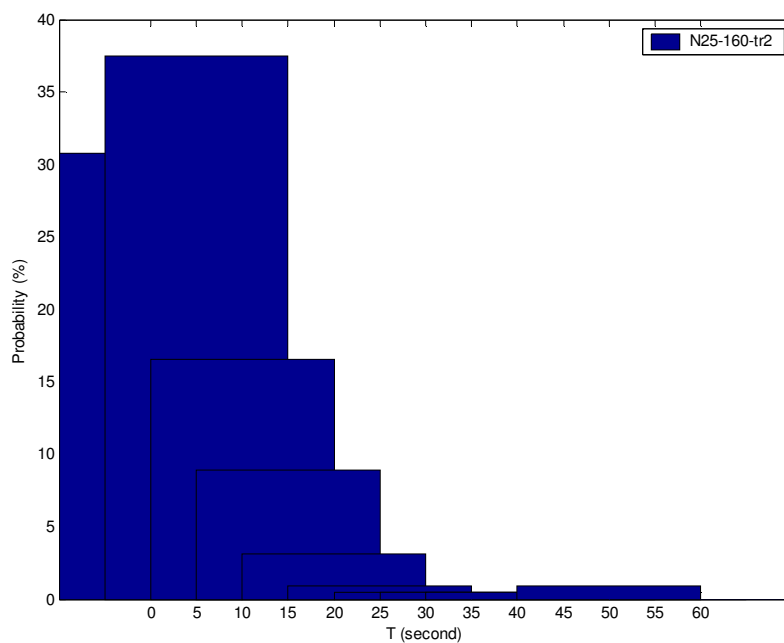

templates.

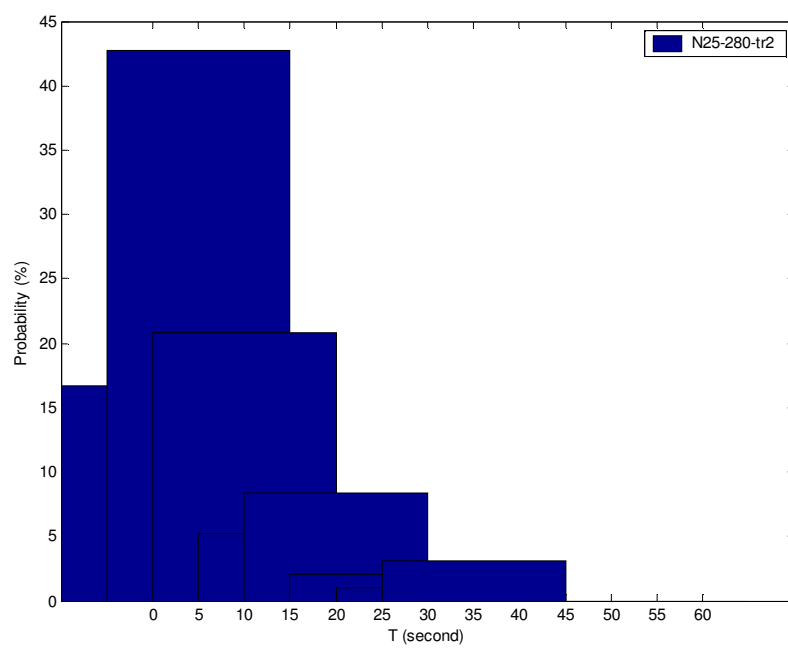

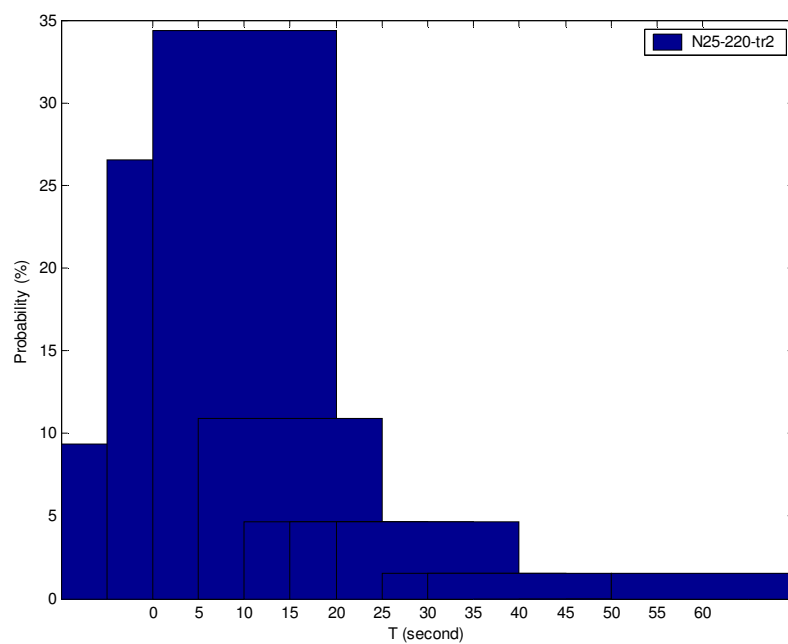

However, these distributions are quite different from the $N25_{\text{antiDSR}}$ promoter (Figure 8-6). The lifetime distribution of initial transcription state on the $N25_{\text{antiDSR}}$ promoter has more populations with a longer lifetime than the N25 promoter.

DNA template	N25-160-tr2	N25-220-tr2	N25-280-tr2	N25-340-tr2	N25 *	$N25_{\text{antiDSR}}$ -160-tr2
T (second)	9 ± 8	14 ± 11	11 ± 8	15 ± 11	11 ± 10	69 ± 64

Table 8-2

The lifetime was obtained by fitting the data from N25-160~340-tr2 with removing outliers.

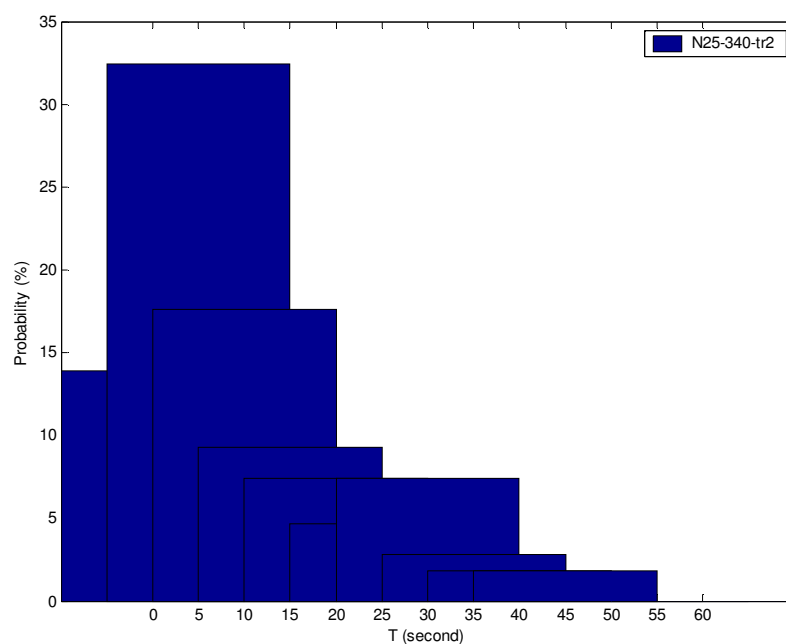

Figure 8-4

The distribution of the lifetime of abortive initiation state for each N25 promoter DNA template is very similar. The distributions shown here are normalized. (See Appendices A, B, C and D)

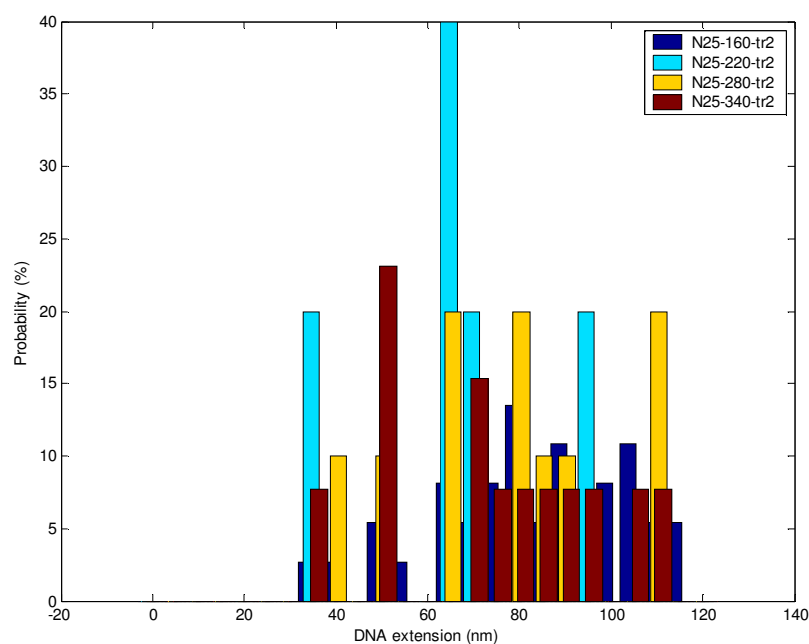

Figure 8-5

The distributions shown here indicate that DNA extension was not affected by the downstream sequence of N25 promoters. The distributions are normalized. (See Appendices A, B, C, and D).

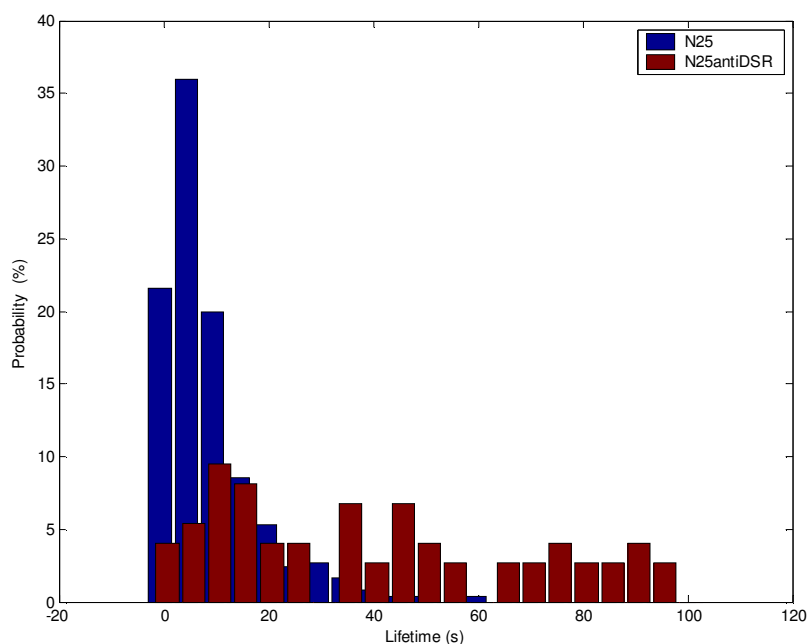

Figure 8-6

The lifetime distribution of initial transcription on N25antiDSR-160-tr is broad, On the contrary, the distribution of initial transcription is sharp on the N25-160~340-tr2 DNA templates. This distribution has been normalized. (See Appendices A, B, C, and D).

Interestingly, the distribution of DNA extension caused by ITC formation on N25_{antiDSR} promoter has two peaks (Figure 8-7). If a peak can represent a population of a intermediate, this seems to imply the presence of two intermediates populations on the N25_{antiDSR} promoter during abortive initiation. The distribution of ITC on the N25 promoter has only a single peak.

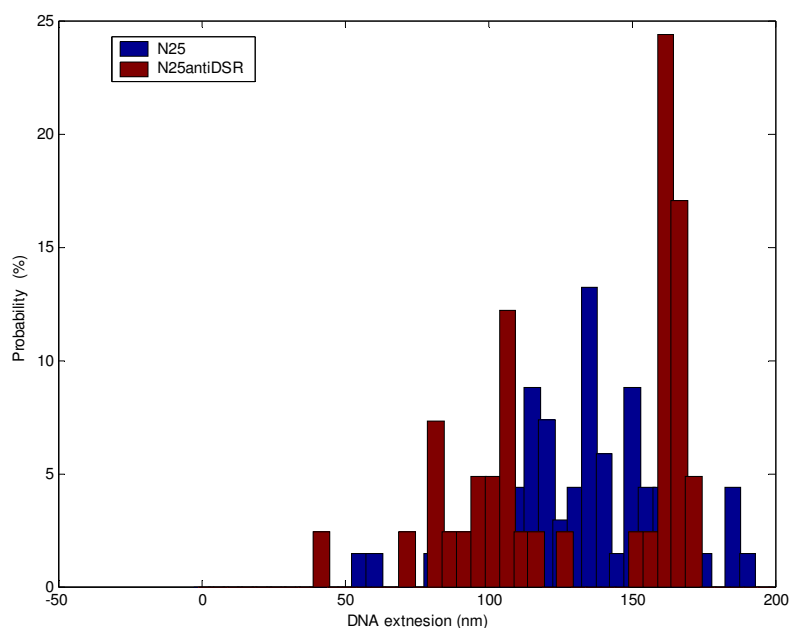

Figure 8-7

The distribution of change in DNA extension caused by the formation of ITC on the N25 promoter and the N25_{antiDSR} promoter. The distributions here are normalized. (See Appendix A and F)

8.3.3 Elongation and termination on the N25 promoter and N25_{antiDSR} promoter

The results of the elongation plus the termination time for the N25-160-tr2 construct and the N25_{antiDSR}-160-tr2 construct are shown in Figure 8-8 and Table 8-3.

	N25-160-tr2	N25 _{antiDSR} -160-tr2
T(second)	19 ± 10	18 ± 6

Table 8-3

The elongation plus the termination time on N25-160-tr2 and N25_{antiDSR}-160-tr2

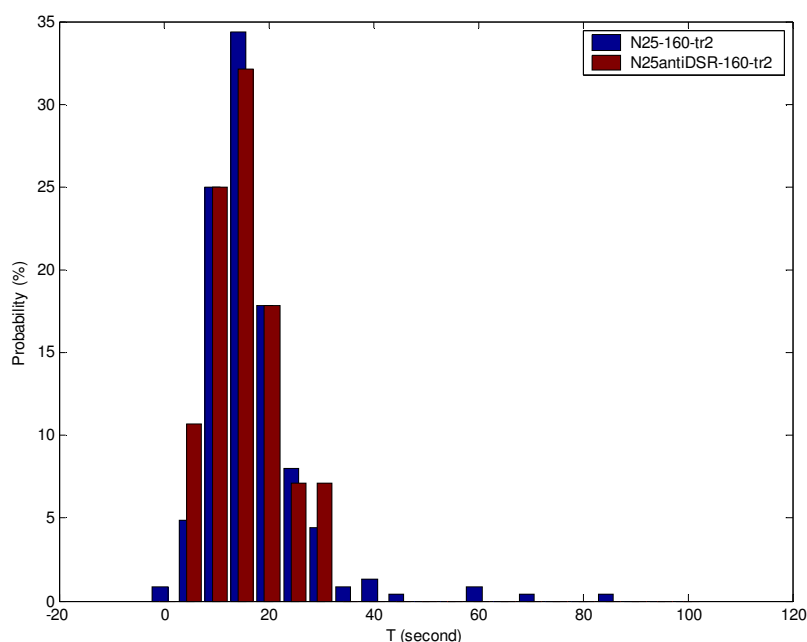

Figure 8-8

The distributions of elongation time plus termination time on N25-160-tr2 and N25_{antiDSR}-160-tr2. The distributions are normalized. (See Appendix A and F)

Although the N25-160-tr2 and the N25_{antiDSR}-160-tr2 have different promoters, it is clear that the elongation time plus termination time for the two DNA templates is very close, their distributions are almost identical for the two DNA templates. In addition, the DNA extension change caused by the formation of TEC were the same for N25-160-tr2 and N25_{antiDSR}-160-tr2 (Figure 8-9) (Table 8-4).

	N25-160~340-tr2	N25antiDSR-160-tr2
DNA Extension (nm)	58 ± 12	65 ± 10

Table 8-4

The DNA extension caused by the formation of TEC on the N25 promoter and the N25_{antiDSR} promoter

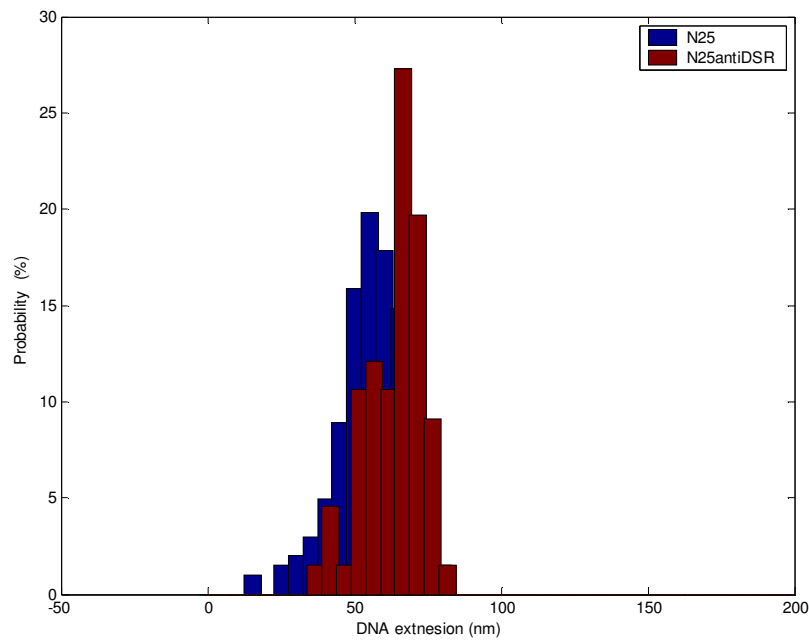

Figure 8-9

The distributions of DNA extension was caused by the formation of TEC on the N25 promoter and the N25_{antiDSR} promoter

8.4 Conclusions

The difference between the N25_{antiDSR} construct and the N25 construct is the ITS, which is involved with DNA scrunching. The result here implies that ITS alters the kinetic energy barrier for promoter escape. The distributions of bubble size, DNA compaction are different, reflecting difference in stressed intermediates during initial transcription. The difference in promoter, however, does not affect the rate of transcription elongation once RNAP has escaped the promoter. In addition, the result implies that the time of a promoter rewinding event is much shorter than the

elongation and termination time because difference ITS des not affect the kinetics of elongation and termination.

Chapter 9

Determination of the effects of elongation factor GreB on initial transcription and promoter escape

9.1 Background and Objectives

A moribund complex is an ITC which cannot generate full length of RNA products [3]. Some of ITCs can only generate nascent RNA. Such ITCs are called moribund complex. It has been shown that GreB can reduce the number of moribund complexes at transcription initiation. Instead the moribund complex will enter an arrested state with short RNA transcripts [3].

It has also been shown that GreB can reduce the lifetime of transcription initiation by 2~5 fold on the N25 promoter [2]. In this chapter, we studied the kinetics of transcription initiation and elongation on the N25 promoter in the presence and absence of GreB.

9.2 Experimental design and methods

We used the N25-160~340-tr2 DNA templates to determine the kinetics of transcription with GreB by including GreB in the transcription assay. The N25-100-tr2 DNA template was used to determine transcription kinetics in the absence of GreB. The design of N25-160~340-tr2 is shown in Figure 7-1 and N25-100-tr2 is shown in Figure 4-1.

The methods to determine the lifetime of the abortive initiation state and the lifetime of elongation were the same as in Chapters 8. We also used the same method to measure the changes of DNA extension on these DNA templates. All of the data were processed in the same manner as in Chapter 8.

9.3 Results

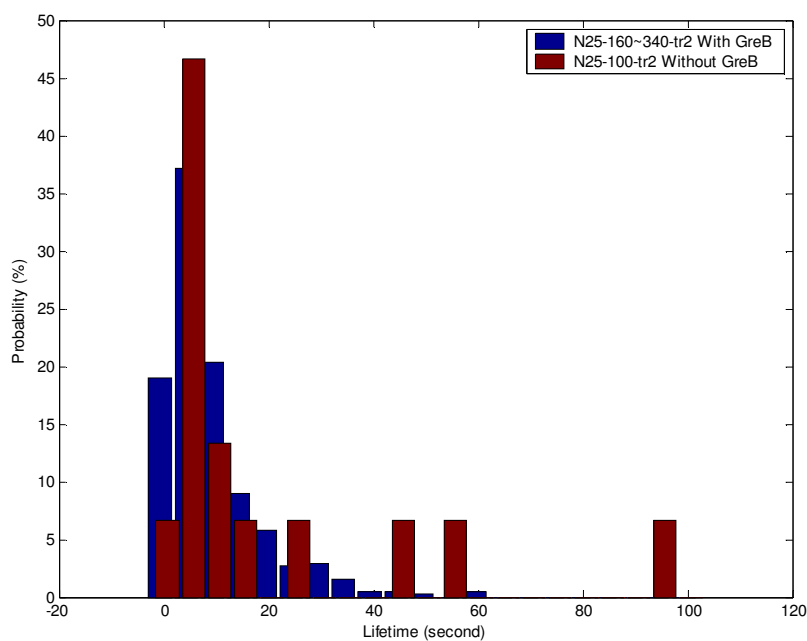

9.3.1 Abortive initiation with/without GreB

In our study, upon addition of GreB into the transcription assay, the lifetime of ITC was reduced by one half (Table 9-1). The populations of ITC with longer lifetimes for the N25 promoter in the presence of GreB decay quickly (Figure 9-1).

	N25-160~340-tr2 with GreB	N25-100-tr2 without GreB

Table 9-1

The lifetime of abortive initiation on the N25 promoter with and without GreB

**Figure 9-1**

The lifetime distribution of the abortive initiation state on the N25 promoter with and without GreB. (See Appendices A – E)

Changes of DNA extension are proportional to the transcription bubble size or DNA compaction. The transcription bubble size or DNA compaction was not significantly affected by the presence or absence of GreB (Table 9-2). The amount of data used to determine the kinetics in the presence of GreB is much more than that

used in the absence of GreB. In the both cases, however, the change of DNA extension caused by ITC formation has similar values, and one is still able to observe similarity between the two distributions. Figure 9-2 shows the l_{obs} does not change much with the N25 promoter during transcription in the absence of GreB in the presence and absence of GreB.

9.3.2 Elongation and termination with and without GreB

The DNA extension caused by the formation of elongation complex is almost the same in the presence or absence of GreB (Table 9-3) (Figure 9-3). This implies that the bubble size or DNA compaction of TEC are not be affected by GreB.

The DNA extension caused by the formation of TEC on the N25 promoter with and without GreB

**Figure 9-3**

The distributions of DNA extension caused by the formation of ITC on the N25 promoter with and without GreB. (See Appendices A – E)

9.4 Conclusions

These results clearly indicate that GreB enhances promoter escape during the abortive initiation step, and the lifetime of abortive initiation state is sensitive to the presence of GreB. Since the lifetime of abortive initiation can correspond to the

number of abortive initiation cycles, these results show that GreB can reduce the number of abortive initiation cycles. Alternatively, the long lifetime state may correspond to a moribund complex, with GreB restoring the complex to a productive complex. The results also indicate that GreB does not affect the size or DNA compaction of ITC and TEC. It has been shown that GreB reduces the abortive probability of nascent RNA products [1]. Therefore, GreB may play the same role during abortive initiation as in transcription elongation- it helps to activate the backtracking complex and regenerate the active site of RNAP.

Chapter 10

Materials and Methods

10.1 The construction of plasmid DNA templates

pARn25-100-tr2 (pARn25_{antiDSR}-100-tr2) and its multiple 60 base pair insert derivatives were used as transcription templates in this study. All of these templates had a *tR2* terminator and T5 N25 or N25_{antiDSR} promoter. They varied in the number of copies of a 60 bp DNA fragment, which contained +13 to +66 of the transcribed region of N25-100-tr2.

These pARn25-100-tr2 (pARn25_{antiDSR}-100-tr2) derivatives plasmids were prepared by digesting pARn25-100-tr2(pARn25_{antiDSR}-100-tr2) with Nru I restriction enzyme, and inserting varying numbers of a 60 bp DNA fragment. The 60 bp DNA fragment was obtained from the PCR product of the N25-100-tr2 (pARn25_{antiDSR}-100-tr2) construct, which was treated with EcoRV at both ends (Figure 5-1). The two DNA primers – pARn25for and pARn25rev - were used in the PCR reaction. The 60 bp piece of DNA was ligated into pARn25-100-tr2

(pARn25_{antiDSR}-100-tr2) in a molar ratio of 150:1, resulting in multiple 60 bp inserts.

The plasmid were transformed into Stbl2 competent cells, and plated on ampicillin.

The clones were selected and sequenced to determine the exact number of inserts.

10.2 The construction of DNA fragment for nanomanipulation

In order to construct the DNA fragment for the nanomanipulation experiment, the segments in (Figure 4-1) were obtained from the PCR products of the pARn25-100-tr2 (pARn25_{antiDSR}-100-tr2) plasmid or its multiple 60 bp insert derivatives add-on primers – MluI PROC4050 and NotI PROC2050. The length of the resulting DNA construct was around 2kb.

After treating the 2kb piece of DNA with the restriction enzymes - MluI and NotI, the DNA fragment was ligated with 1kb biotin labeled DNA on one extremity and 1kb digoxigenin labeled DNA on the other extremity. The biotin-labeled DNA fragments were prepared via PCR amplification of pARn25-100-tr2 with the primers MluI RPOC4050 and RPOC 3140, along with Biotin-16-dUTP, and were subsequently digested with MluI. Similarly, the digoxigenin-labeled DNA was

prepared by amplification of pARn25-100-tr2 with NotI PROC50, RPOC820 and Digoxigenin-11-dUTP, and was digested with NotI.

The sequences of the primers used are below:

pARn25for:

5'-GAGAGAGATATCGAGGAGTTTAAATATGGCTGGTTCTCGCG-3'

pARn25rev:

5'-GAGAGAGATATCGATTGGGATGGCTATTCGGAATTC-3'

MluI PROC4050:

5'-GAGAGAACGCGTGACCTTCTGGATCTCGTCCACCAGG-3'

NotI PROC2050:

5'-AGAGAGCGGCCGCGAGAAGATCCGCTCCTGGAGCTACG. -3'

RPOC50:

5'-GAGAGAGCGGCCGCGAGAAGATCCGCTCCTGGAGCTACG-3'

RPOC820:

5'-TCCTGGCGCAGGTAGATGAG-3'

PROC3140:

5'-CTGATGCAAAAGCCCTCGGG-3'

10.3 Preparation of the Capillary

A square glass capillary, (1×1×50 mm) was immersed in nitric acid for 4 hours and rinsed with an excess amount of water. After drying, the inside of the capillary was coated with 0.1% polystyrene (w/v) in toluene, and dried with nitrogen.

The dried polystyrene coated surface of the capillary was injected with 100 µl PBS containing 0.1 mg/ml polyclonal anti-digoxigenin. The capillary was incubated with the polyclonal anti-digoxigenin solution for 24 hours at 37 °C. A blocking solution containing 10 mg/ml BSA and 3.3 mg/ml of polyglutamic acid, 25 mM Hepes NaOH, pH 7.9, 75mM NaCl, 10 mM MgCl₂, 0.1% Tween 20, and 10 mM 2-mercaptoethanol was injected into the capillary and incubated for another 24 hours. The capillary with blocking solution was washed with 1×PBS. Polystyrene beads was injected into the capillary and allowed to settle. After sedimentation of these beads, the capillary was washed by SB buffer until nonbinding beads were removed. A 15 µl aliquot of DNA-anchored beads was injected into the capillary. The DNA anchored beads attached to the capillary surface through interaction of digoxigenin and anti-digoxigenin. After washing the capillary surface with a sufficient amount of SB buffer, most of the nonspecifically attached beads were removed.

10.4 Calibration and Data Acquisition

The magnets were loaded to a z axis position where the stretching force did not denature the DNA. The magnets were rotated causing a known number of superhelical turns to be introduced into the DNA molecule, with which we were interested. In order to determine the position of the beads, a calibration was made for the position of an object, as described in Figure 3-3. This was used to determine the l_{obs} . For each particular superhelical turn, the l_{obs} was collected from averaging every l_{obs} over a period of time. The length of acquisition time depended on the signal to noise ratio. With various superhelical turns, the curve of the superhelical turn vs. the l_{obs} of the DNA molecule was obtained (Figure 2-9). Superhelical turns were introduced into the DNA and made the corresponding $\sigma = 0$. At this supercoil-free state, by adjusting the z positions of the magnets, the fluctuations of the magnetic bead and l_{obs} were determined. The magnitude of the stretching force and the persistent length of the DNA were extracted from the fluctuation and l_{obs} measurement.

The DNA molecule was rotated to a region of constant torque (usually superhelical density= ± 0.021), and the z position of magnets was adjusted to a position

at which the applied magnetic force was around 0.3 ± 0.03 pN. The capillary was washed with a solution containing: 25 mM Hepes NaOH, pH 7.9, 150 mM (75mM) NaCl, 10 mM $MgCl_2$, 0.1% Tween 20, 0.1 mg/ml BSA and 10 mM 2-mercaptoethano. In the buffer, a curve for superhelical turns vs. l_{obs} was taken, which was used for the determination of the constant torque region of the DNA molecule. The sample was injected into the capillary, and data acquisition was begun.

10.5 Transcription Assay

The transcription assay uses 25 mM Hepes NaOH, pH 7.9, 75mM NaCl, 10 mM $MgCl_2$, 0.1% Tween 20, 0.1 mg/ml BSA, 10 mM 2-mercaptoethanol and contains 10~1000 pM RNAP, 1 μ M GreB and 15nM sigma 70 with various concentration of NTPs. The transcription assay was injected into the capillary. The concentrations of RNAP used in the experiments were determined by the frequency of transcription events as the sample was injected.

In order to study the role of GreB, in some control experiments we did not add GreB into the sample solution. The role of sigma subunit here was to prevent the sigma 70 of the RNAP Holoenzyme from dissociating.

10.6 Buffer used in the experiments

PBS buffer:

Phosphate-buffered saline

SB buffer:

10 mM potassium–phosphate buffer, pH 8,

0.1 mg/ml BSA,

0.1% Tween 20

Appendix:

Appendix A: N25-160-tr2

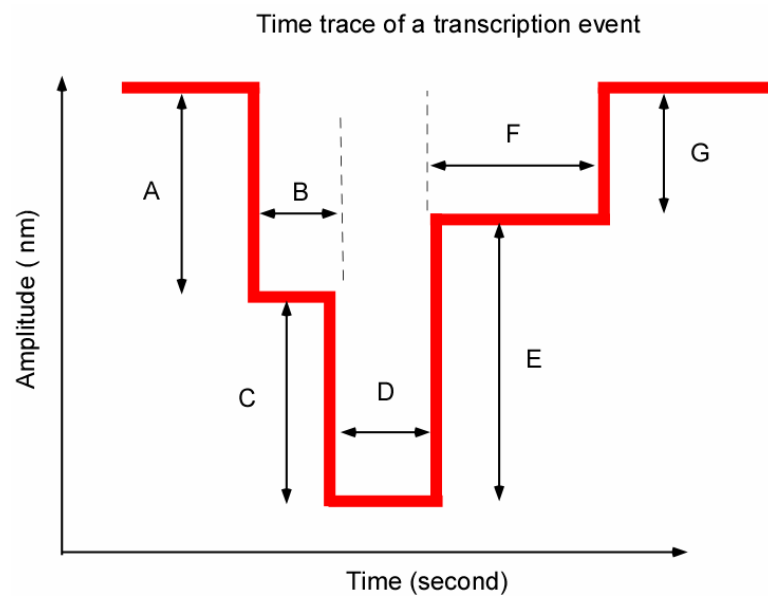

Appendix B: N25-220-tr2

Appendix C: N25-280-tr2

Appendix D: N25-340-tr2

Appendix E: N25-100-tr2 without GreB

Appendix F: N25_{antiDSR}-160-tr2

The time trace of a complete transcription event can be observed in (Figure 6-2)

Curriculum Vitae

Chen-Yu Liu

1994.10~1998.6

Undergraduate student, Chemistry Department, National Tsing Hua University

1998.6~2000.7

Graduate student, Chemistry Department, National Taiwan University

2000.10~2000.12

Research assistant, The Institute of Biological Chemistry, Academia Sinica

2000.12~2000.1

Military service

2001.2~2001.6

Research assistant, The Institute of Biological Chemistry, Academia Sinica

2001.8~2002.8

Teaching assistant, Chemistry Department Taiwan University

2002.10~2003.6

Research assistant, The Institute of Chemistry, Academia Sinica

Graduate student, Biophysics and Computational Biology , Rutgers University, New Brunswick 2003.8~2007.7

Advisor: Richard H. Ebright

Publication:

Andrey Revyakin, Chenyu Liu, Richard H. Ebright, and Terence R. Strick, ' ABORTIVE INITIATION AND PRODUCTIVE INITIATION BY RNA POLYMERASE INVOLVE DNA SCRUNCHING, *Science*, **2006**, 314,1033
