ABSTRACT OF THE DISSERTATION

Time-resolved fluorescence studies of protein aggregation leading to amyloid formation

by Jason Thomas Giurleo

Dissertation Director: David S. Talaga

Aggregation of soluble polypeptides or proteins into insoluble amyloid fibrils containing the cross-β structural motif has been observed in the progression of over 20 diseases. Self-assembly mechanisms have been proposed but are not well-established. Recent evidence has shifted some of the focus from amyloid fibrils to prefibrillar amyloidogenic aggregates as the cause of disease symptoms. We used time-resolved non-covalent fluorescence labeling to follow the conformational changes occurring in a model protein (β-lactoglobulin) during amyloid aggregation. The data was analyzed using a novel model-free globally regularized fitting technique. This reduction of model space allowed for stable fitting and the ability to identify intermediate species. An aggregation model was then proposed. In the second half of this thesis, our attention is shifted to α-synuclein (αSyn). αSyn is the majority protein component of the fibrillar inclusion bodies found in brains of Parkinson's disease patients. We have begun a set of fluorescence lifetime experiments using covalent and non-covalent labeling schemes to elucidate the dynamic, conformational and aggregation properties of αSyn.

Acknowledgements

Acknowledgements begin with my mentor, Professor David Talaga. As a dance instructor, he taught me my first steps of Lindy Hop, well before either of us began here at Rutgers. As a mentor, I thank him for pushing me as hard has he pulled for me. I would like to thank my committee: Professors Barbara Brodsky, Ronald Levy and Edward Castner. I would especially thank Ed for all of the insightful conversations and for the use his laser system to take most of the time-resolved fluorescence data presented in this dissertation. I am indebted to Researchers Dave Remeta and Conceicao Minetti who been so generous with their time; "helpful" is not a strong enough word. I would like to thank the Talaga research group: Troy Messina, Jeremy Pronchik and Xianglan He. Whether directly or indirectly, each has contributed in some way to this work by selflessly donating their time. More importantly, their sense of humor pulled me through the frustrating moments (or **HAM** as we called it). The support my family was paramount. First, Aunt Noelle and Uncle Greg for the engaging conversations, a place to crash, and their uncanny knack for instilling confidence in my path. Second, my girlfriend Dorothy whose emotional support has kept my mind focused while not letting me burn out. Many of the hours spent in Starbucks writing, she was right by my side helping in which ever way should could. Lastly, I acknowledge my parents. My well-being has always been a top priority along with their unconditional emotional support. Okay, and some financial support too ;) And to my mom: You took on the colossal task of proofreading this dissertation without question, just like you did 18 years ago when you helped prepare, proofread, and type my first science project. See, it was all worth it!

Chapters 2 and 3 where previously published in the The Journal of Chemical Physics, 128:114114(118), 2008 and Journal of Molecular Biology 381:13321348, 2008, respectively. The author of this dissertation was the primary author of two contributing publications.

Dedication

Essay as part of my application to The College of New Jersey (circa February 1995):

The person who has had a significant influence in my life is Thomas Puglisi. He is a kind, loving and patient man.

As a child my favorite place was his basement workshop where we would conduct "Mr. Wizard"- type experiments. As I watched eagerly, he patiently would answer my many questions, never making my inquiries seem frivolous. I loved observing him fix things, and many times he would trust me with his tools. He always would listen to my ideas and opinions about possible solutions. Tom taught me problem solving by having me look at a situation from many different angles. I learned that nothing should be overlooked, no matter how simple or obvious. Problem solving not only became challenging, but also rewarding. I still treasure the small, self-propelling, wooden toys we made together. Now, after studying physics, I realized that he applied complex laws of physics to make a simple toy! As I grew older, and several school projects later, I began to appreciate his methodical, practical, and efficient approach to making or fixing something. I would revel in drawing up plans with objectives and then seeing them become a reality Tom's gentle guidance through my trial and error process, without criticizing me for mistakes, gave me the confidence to keep trying.

Early on, Tom Puglisi sparked a curiosity in me about the complex worlds of chemistry and physics. He taught me that patience, determination, creativity, and imagination are the keys to a successful outcome. I am proud to say that the man who has significantly influenced my life and my desire to become a scientist

is my grandfather, Thomas Puglisi.

Tom (1917-2002) was a chemist for Hoffmann-LaRoche for 43 years including a three year hiatus serving as an Army Sargent, stationed on the European front under General Patton. Tom passed away from complications of Alzheimer's disease, and is to whom I humbly dedicate this work.

Chapter 1

Introduction

Personal motivation

Truth be told, I was resoundingly disinterested in pursuing a research career studying biological molecules after graduating from college. It was during my employment at Hoffmann-La Roche that I became aware of the importance of increasing the stability and shelf life for protein-based therapeutic agents. Aggregation was usually the biggest culprit in reducing the long-term efficacy of a drug; we worked closely with the formulators to curb this effect. Concurrently, protein aggregation research was becoming a popular topic, specifically because a small peptide was found to be the main constituent of proteinaceous plaques found in Alzheimer's disease. [1, 2] The topic became personal when my grandfather was diagnosed with this devastating disease. Motivation to study the physics and chemistry of biological molecules stemmed from these events.[1] This dissertation is presented as the product of this motivation.

Disease

In the mid-1800s, German physician Rudolph Virchow first coined the term "amyloid" after iodine staining an abnormally appearing cerebral corpora amylacea tissue culture. In 1906, Alois Alzheimer autopsied the brain of a patient who exhibited premature senile dementia, along with paranoia and agitation, and found

---

[1]I also had an interest in inorganic chemistry but was throughly thwarted by enlisting in one Solid State Chemistry course at Rutgers University as a non-matriculated student in the spring of 2000. Professor's name withheld.

neurofibrillary tangles and amyloid plaques. [3] In 1912, a colleague of Alzheimer, Friedrich Heinrich Lewy, discovered protein inclusion bodies in the brains of patients with paralysis agitans. [4] Later, it was discovered that the inclusion bodies also contained fibrillar protein deposits. Since these discoveries, 20 protein aggregation diseases, including Alzheimers disease (AD), Parkinsons disease (PD), type II diabetes, and Creutzfeldt-Jakobs disease, have been observed. The diseases have a common thread: soluble polypeptides or proteins aggregate into insoluble amyloid fibrils containing the cross-β structural motif. The enormous medical implication of these diseases has motivated research and numerous reviews discussing the structure and growth of amyloid fibrils. [3, 5, 6, 7, 8, 2, 9, 10, 11]

PD affects 500,000 people in the United States. This is the second most prevalent of the late-onset neurodegenerative diseases. [12] Today the disease is clinically diagnosed much like it was done prior to Virchow's amyloid discovery. James Parkinson wrote an extensive essay on "Shaking Palsy" in 1817 (reprinted in Ref.[13]) describing a patient with involuntary muscle tremors and inability to initiate movements. Pathologically, PD is characterized by the predominate loss of dopaminergic neurons in the substantia nigra. Dopamine, which is crucial to human movement, is manufactured in this part of the brain. Upon autopsy, it has been shown that some neurons have fibrillar cytoplasmic inclusions, or Lewy bodies. [12] It is not clear, however, if the the presence of Lewy bodies and fibril formation is the cause or the consequence of the neuronal death.

Recent evidence has shifted some of the focus from macroscopic fibrillar deposits to prefibrillar amyloidogenic aggregates as the cause of symptoms[14, 5, 15, 9], leading many to propose development of vaccines targeting small amyloidogenic aggregates.[7, 16, 2] In the case of PD, it has been shown that neurons containing Lewy bodies appear to have no quantifiable differences in viability.

Secondly, the amount of Lewy bodies found in postmortem brains of asymptomatic patients is ten-fold greater than the prevalence of PD. Thirdly, early-onset familial forms of PD lead to neurodegeneration without substantial Lewy body accumulation. [12] One hypothesis suggests that inclusion bodies sequester toxic mis-folded or aggregated protein species from the system, akin to a protein vacuum cleaner-like mechanism. [14] Transgenic animal experiments showed that overexpression of the principle protein found Lewy bodies was not concomitant to neuronal loss. However, transgenic mice with non-fibrillar deposits in parts of the brain did exhibit substantial neuronal deficiencies. [9]

Placing the responsibility of the disease on toxic oligomers makes the solution to the aggregation problem hard to ascertain. Proposed aggregation mechanisms are constructed around the *in vitro* studies that show a sigmoidal growth of amyloid fibrils. The kinetics of the mechanism have been named lag, growth and elongation (as labeled in Fig. 6.1). This may lead us to the notion that the mechanism of protein aggregation simple.
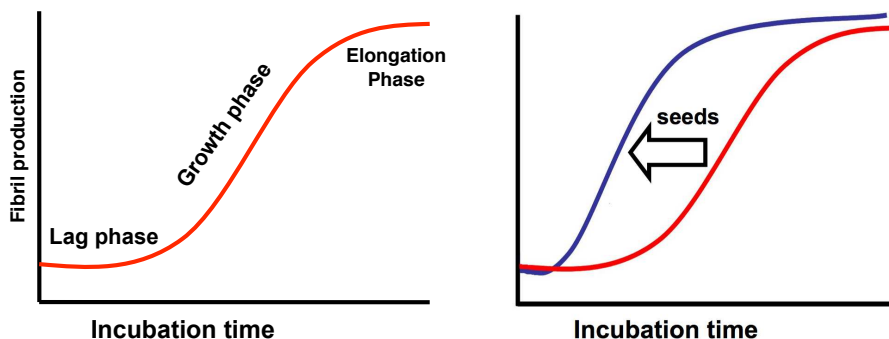

Figure 1.1: *Classic sigmoidal kinetics of amyloid fibrils in vitro.* Left panel: The canonical explanation of amyloid growth has been proposed from histological staining assays *in vitro*. The explanation involves three phases: lag, growth and elongation. Right panel: Adding pre-formed seeds eliminates the lag phase. [17] See Fig. 1.2 for a comprehensive description of the possible intermediates that have been proposed.

To the contrary, monitoring amyloid formation is only a small part of the entire
Figure 1.2: *Overview of amyloid assembly mechanisms.* **Amyloid)** any fibril, plaque, seed, or aggregate that has the characteristic cross-β sheet structure. **Amyloid fibril)** long ribbons of amyloid approximately 10 nm in diameter and >100 nm in length. Most often observed in vitro. **Amyloid protofibril/filament)** a species of amyloid smaller in diameter (3-6 nm) and length (<100 nm) than typical for amyloid fibrils, thought to be a possible direct precursor to amyloid fibrils perhaps through lateral aggregation. **Amyloid seed (or template))** a species of a critical size or structure that rapidly elongates to form larger amyloid species possibly by providing a proper scaffold for amyloid assembly. **Amyloidogenic oligomer)** A small aggregate of precursor that is smaller than the critical seed size but still may have some of the structural characteristics of amyloid. **Folded state)** The native (functional) state of the precursor. **Folding intermediate)** A partially folded or misfolded structure of the precursor. These partially folded structures are potentially the same as or precursors to amyloidogenic folds. **Denatured state)** The unfolded state of the precursor. **Unstructured aggregate)** Completely or partially denatured proteins tend to aggregate non-specifically without forming a particular structural motif.

mechanism, and the vagueness in the sigmoidal kinetics can allow for many different possible mechanistic intermediates. Fig. 1.2 is a comprehensive diagram of proposed intermediate species and pathways along the amyloid formation mechanism. It is well accepted that critical intermediates exist along the amyloid pathway, but have not been explicitly identified. This combination has led to

a wide range of plausible mechanisms that do not violate sigmoidal growth of amyloid fibril. Our interest is to shift focus from amyloid fibrils to prefibrillar amyloidogenic aggregates that are present in the lag phase. Only by elucidating the intermediate species can an accurate mechanism be developed. Unfortunately, intermediate species are expected to be in relatively very low concentration. We set out to confront this obstacle by utilizing several biophysical techniques including time-resolved fluorescence (TRF) spectroscopy, dynamic light scattering (DLS), and atomic force microscopy (AFM).

β-Lactoglobulin studies

In chapter 3, we investigated the aggregation and amyloid fibril formation of β-lactoglobulin variant A (β-LGA) under partially denaturing conditions. T0his protein has been very well studied [18] and is fairly inexpensive. β-LGA is a member of the lipocalin superfamily of proteins consisting of a flattened β-barrel or calyx comprised of eight β-strands (Fig. 3.1). We took advantage of the naturally occurring hydrophobic pocket for the intercalation of an environmentally sensitive fluorescence probe, ANS. The modulation of the fluorescent properties reflected conformational changes of the protein along the aggregation pathway.

The fluorescent lifetime for any particular time of incubation needed to be represented by a multi-exponential function, suggesting multiple binding species were present. By locally fitting each incubation time point, it was obvious that there were trends in the data. This allowed for a global model fitting approach. It was a rigorous search, taking many iterations, but eventually a statistically significant simple global model was selected and shown in Eq. 1.1,

$$I_D(t) = A_D(f_1 e^{-t/\tau_1} + f_2 e^{-t/\tau_2} + f_3 e^{-t/\tau_3} + (1 - f_1 - f_2 - f_3)e^{-t/\tau_4}) \qquad (1.1)$$

where A_D was the total time-zero intensity for a particular day (local), $f_1, f_2,$ and f_3 were the fractional amplitude components (local), and τ_1, τ_2, τ_3 (global), and

τ_4 (local) were the lifetimes.
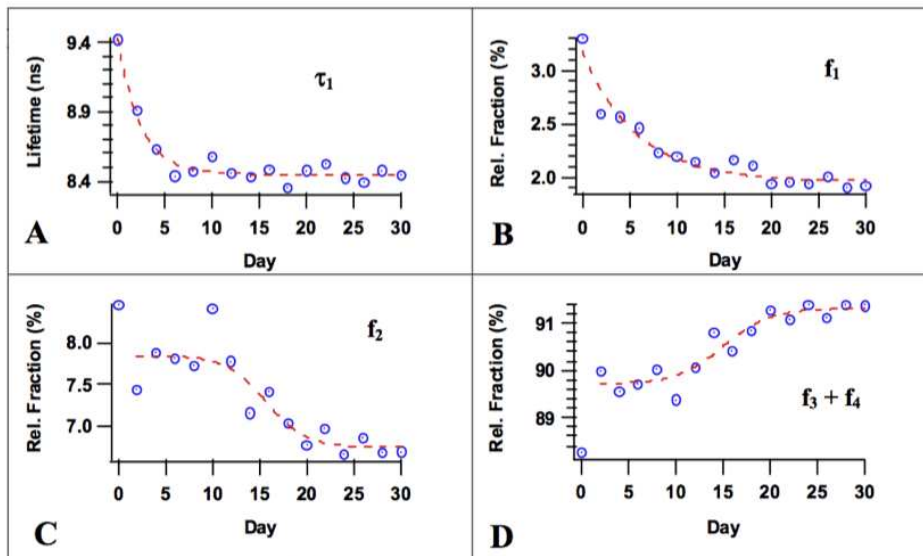

Figure 5A-D. ANS binding to β-LG. Globally fit parameters over the incubation: **A)** lifetime of calyx binding, τ_1; **B)** fraction of calyx binding, f_1; **C)** fraction of exterior binding, f_2, **D)** free ANS fractions, f_3 + f_4. Dashed lines are to guide the eye.

Figure 1.3: *Fit parameters of Eq. 1.1 used to described lifetime data of ANS bound BLG.* This figure was originally part of my thesis proposal and is shown to illustrate the parameter trends after a global model was selected.

This analysis was presented as part of my research proposal as a requirement for Ph.D. candidacy. The parameters from the global fit are shown in Fig. 1.3 and originally part of the proposal. The speculative mechanism was proposed based on the data and is shown in Fig. 1.4. The mechanism was chosen based on interpretation of the data which heavily relied on the global fit to reduce the model space. Though we believed that the global model was supported by the data, we understood that model selection is also related to the skill (and patience) of the investigator selecting the model. This prompted us to think about ways to develop (and not select) a model without unknowingly forbidding the true solution.
Fig. 7. Chemical Kinetics Simulator, v 1.01. A concentration dependence of species using the working model for amyloid formation.

Figure 1.4: *Fit parameters of Eq. 1.1 used to described lifetime data of ANS bound BLG. This reduced data set originally appeared in my thesis proposal.* τ_1 *and* f_1, *and* τ_2 *and* f_2 *are attributed to sites 1 and 2, respectively.* τ_1 *decreases with increasing denaturant concentration, indicative of the disruption of the binding pocket. At time-zero incubation, we assume that the protein is soluble but in a non-native state, S. During first six days, the site 1 lifetime decreases is indicative of a further conformational change. S-state is converted to that of an aggregation prone state, A. The overall decrease in ANS binding to site 1* (f_1) *may be due to a further conformational change as A-state monomers aggregate to O-state oligomers that lack the internal binding pocket. It is also conceivable that the inablitiy for ANS to bind site 1 is a function of steric hindrance due to A-state aggregation and not a conformational change in the binding pocket. The site 2 binding occurs via external hydrophobic interactions. It is expected that any hydrophobic exterior patches will be utilized by protein-protein interactions of amyloid aggregation but may be affected by general oligomerization. By day 12, ANS external binding to site 2 becomes in competition with the specific protein-protein interactions necessary for amyloid cross-β structure, AM.*

Using global probabilistic constraints to develop global models

Spectroscopic techniques often involve making a measurement on a system, making a small perturbation to the system by some experimental factor, and then taking another measurement. When done in this way, a smooth change in the signal is expected. In chapter 2, we take advantage of this prior knowledge to circumvent the need to reduce model space in a single step. Instead, we develop an approach that allows one to start from an essentially model-free fit and progress to a specific model by moving from probabilistic constraints (parameter continuity across the experimental coordinate) to deterministic constraints (global models).

In chapter 2, the globally regularized interior-point gradient method (GIPG) is developed.[2] We demonstrate through a pedagogical example, that GIPG could represent a complex distribution of species on par with those thought to be present during protein aggregation. Furthermore, we show how a maximum entropy method approach may claim to be "model-free", but does not significantly help model development.

β-LGa revisited, model solidified

Chapter 3 is the recapitulation of the β-LGA data sets using GIPG analysis to generate global models. By utilizing GIPG, lifetime evolution distributions were calculated. We assumed that the contributions of different ANS-bound species could be expressed as a linear combination of multipeaked "fingerprints". This type of fingerprint analysis, to our knowledge, is the first of its kind to be applied to TCSPC data.

Time-resolved thioflavinT (ThT) luminescence was also analyzed by GIPG. DLS data was fit with GIPG by adding a continuity condition to the particle size

---

[2]Chapter 7 is the explanation of the final version of the algorithm. Previous versions were computationally inefficient, but fully functional. By utilizing three dimensional matrix operations, a drastic increase in the computational speed was reached.

distribution evolution. Though specific global models were not independently developed for ThT and DLS data, the trends were considered when generating fingerprints for the ANS fluorescence lifetimes.

The comprehensive interpretation of all the data led to an aggregation model (Fig. 3.11) and kinetic scheme (Fig. 3.9). We cannot help but notice that the original interpretation of the data did not change much with the inclusion of GIPG analysis and DLS, AFM and ThT lifetime measurements. However, a deeper understanding of the mechanism became available and allowed us to compare our data to other mechanistic possibilities and alternative models.

Spectroscopic studies of covalently labeled αSyn

After comprehensive studies of β-LGA, it was now possible to begin studying α-synuclein (αSyn) with confidence. αSyn is the principle component of Lewy bodies, the protein inclusions bodies that are implicated in Parkinson's disease. One of the similarities carried over from the β-LGA studies is the conformational variability of the monomeric unit. (Recall that β-LGA formed amyloid under partially denaturing conditions.) αSyn is an intrinsically disordered protein (IDP) but upon aggregation, goes through an ordered transition leading to highly ordered cross-β quaternary structure. Amyloid-β peptide (in AD), Amylin (in type II Diabetes) and prion protein (Creutzfeldt-Jakobs) are all intrinsically disordered. [9].

Recent studies have shown that αSyn may have minimal structural preferences. [19, 20]. In these studies, long-range interactions were seen between the negatively-charged C-terminal region with the middle region that is referred to as the non-Aβ amyloid component, or NAC, region of αSyn. A recent NMR study by our collaborator Baum et al., has pointed out that deprotecting the NAC region may lead to transient interchain interactions and may serve as a nucleation site for aggregation. [21]

In chapter 3, we show how the intercalation of a conformationally sensitive fluorophore can report on the aggregation states of a protein. β-LGA was a special case where the host protein has a defined binding pocket. αSyn, on the other hand, is an IDP. It is reasonable to expect that a non-covalent probe would non-specifically bind. Therefore, covalent attachment of the fluorophore is necessary.

In chapter 4, temperature dependence of the fluorescence lifetimes of Alexa Fluor, Atto 590, and Nile Red covalently attached to A19C mutant of αSyn are evaluated. Previously, we have proven that we can analyze complicated fluorescence lifetime distributions with a model-free fitting approach. This approach coupled with the notion that fluorescence is a highly sensitive technique, allows us the unique opportunity to evaluate if, indeed, the fluorescence lifetime can relay valuable information concerning the conformational dynamics of αSyn.

In chapter 5, a more traditional biophysical approach is taken to evaluate conformational changes of αSyn. Specifically, CD and UV absorption are used to monitor the spectroscopic changes αSyn with temperature. The two techniques measure different features of protein. We notice transitions at different temperatures for both techniques. These transitions are evaluated with a two-state model. We invoke a "cooperativity" parameter to be incorporated into the partition function to create a fit function for the data. Cooperativity should be large for folded to unfolded transitions, but for an IDP it is expected to be very close to 1. Spectroscopically, however, the parameter was greater than 1, consistent with the notion that αSyn has local transient conformations. [21]

Aggregation studies of αSyn

While researching the literature for aggregation rates of αSyn, we came across awesome inconsistencies (see Table 6.2). Specifically, aggregation rates were the most affected by preparation and incubation conditions. In chapter 6, we conduct a primary investigation of these conditions. We use the tools developed in

chapters 2 and 3, to evaluate the features in the particle size and ThT lifetimes distributions and relate them to possible aggregation states of αSyn. We also find that certain species along the amyloid pathway are not as pronounced under certain preparation and incubation conditions.

The primary studies of the aggregation mechanism of αSyn is the conclusion of this thesis work. However, it is just the beginning of an exciting set of experiments designed to elucidate the amyloid formation mechanism of a medically relevant protein. First, the proper analysis tools had to be developed (chapter 2) and tested on a model system (chapter 3). With confidence in these tools, the elucidating monomeric properties of αSyn using fluorescence techniques (chapters 4 and 5) could begin.

Chapter 2

Global fitting without a global model: regularization based on the continuity of the evolution of parameter distributions.

2.1   Summary

We introduce a new approach to global data fitting based on a regularization condition that invokes continuity in the global data coordinate. Stabilization of the data fitting procedure comes from probabilistic constraint of the global solution to physically reasonable behavior rather than specific models of the system behavior. This method is applicable to the fitting of many types of spectroscopic data including dynamic light scattering (DLS), time-correlated single-photon counting (TCSPC), and circular dichroism (CD). We compare our method to traditional approaches to fitting an inverse Laplace transform by examining the evolution of multiple lifetime components in synthetic TCSPC data. The global regularizer recovers features in the data that are not apparent from traditional fitting. We show how our approach allows one to start from an essentially model-free fit and progress to a specific model by moving from probabilistic to deterministic constraints in both Laplace transformed and non-transformed coordinates.

2.2   Introduction

Sample heterogeneity is nearly unavoidable in spectroscopy. In many simple systems the heterogeneity can be reduced to the point where it can be ignored. However in complex biological systems there is much to be gained from understanding the heterogeneity. The biological machinery in the cell, for example, relies on the dynamic nature of proteins and protein assemblies.[1] Intermediate species have been identified in protein (mis)folding mechanisms.[2, 3, 4, 5, 6] Multiple conformations of protein-ligand complexes have been discovered because of signal heterogeneity.[7] The evolution of multiple binding sites for β-lactoglobulin and the time-dependence of the site-binding entropy in response to the sudden presence of a strong dipole was elucidated by the heterogeneity in a time-dependent Stokes-shift measurement.[8] Heterogeneity is a crucial element of interpreting single molecule measurements.[9, 10, 11, 3, 12] The presence of multiple species in misfolded β-lactoglobulin leads to very heterogeneous signals prior to[13, 14] and during the assembly of amyloid.[15] To fully understand the underlying physics of such complex systems requires approaches to data reduction that can accommodate their heterogeneity.

Data reduction, or fitting, always requires a model. For any phenomenon being measured there is a set, or space, of models that could reasonably be expected to explain the data. The fitting procedure should eliminate all parts of the model space inconsistent with the data. From the remaining possibilities, the algorithm should allow selection of the most likely model given the experimental information. Experimental information in this context includes both the explicit data that comes from the instrumentation as well as knowledge that comes from the experimental design and understanding of the physics of the system. These two source of information we will call "data" and "prior knowledge."[16]

Prior knowledge is used to determine the model space for the problem. Many

experiments — including quasi-elastic light scattering,[17, 18, 19, 20] circular dichroism,[21] dynamic NMR,[22] and fluorescence lifetime[23] — can be related to their underlying physics by Fredholm integral equations of the first kind:

$$F(t, y) = \int_a^b A(t, k, y) \, f(k, y) \, dk. \tag{2.1}$$

Data inversion seeks to find the function, $f(k, y)$, from the noisy signal, $F(t, y) + \epsilon(t, y)$, given the continuous kernel function, $A(t, k, y)$, that connects t and k, with y remaining untransformed.

The mathematical model space comprises all possible functions $f(k, y)$. In most circumstances the physical interpretation of $f(k, y)$ is that it represents a distribution of populations of species that differ in their values of k. The goal of the experiment is usually to determine the systematic behavior of those populations with experimental changes in y, which can represent any experimental condition such as pH, incubation time, solvent polarity, etc. For example, determining the species population changes with temperature allows thermodynamic parameters to be extracted.

For experiments that monotonically decay such as fluorescence lifetime and dynamic light scattering measurements the kernel in Eq. 2.1 is $A(t, k, y) = \exp(-k\,t)$ and $a = 0$, and $b = \infty$ provide the integration limits for a Laplace transform:

$$F(t, y) = \mathcal{L}\{f(k, y)\} = \int_0^\infty e^{-kt} f(k, y) \, dk. \tag{2.2}$$

Solving for $f(k, y)$ requires inversion of integral equation 2.2.

In the presence of noise, the inverse Laplace transform is not unique. An explicit expression for the inverse Laplace transform[24] illustrates the difficulty of direct inversion,

$$f(k, y) = \mathcal{L}^{-1}\{F(t, y)\} = \lim_{i \to \infty} \frac{(-1)^i}{i!} \left[\frac{i}{k}\right]^{i+1} F^{(i)}\left(\frac{i}{k}, x\right) \tag{2.3}$$

where $F^{(i)}$ is the ith derivative of F. The inverse Laplace transform is sensitive to high order derivatives that do not exist in real data in any meaningful way;

each subsequent derivative increases the appearance of noise. As a result, all functions, $f(k, y)$, that have Laplace transforms, $F(t, y)$, with similar first few derivatives, but divergent higher order derivatives, will be valid solutions to the inverse Laplace transform.

Since direct inversion is problematic, an indirect approach based on least-squares optimization is typical.[25, 26, 27]

$$\min \left[\left(\int_a^b A(t, k, y) f(k, y) \, dk - F(t, y) \right)^2 \right] \tag{2.4}$$

Eq. 2.4, though more stable, still suffers from the problem that multiple solutions for $f(k, y)$ will be statistically equivalent. As a result, the strategy that a particular optimization algorithm uses to obtain the inversion, $f(k, y)$, can influence which solution is found, or *even if* a solution is found.

Many algorithms exist to solve the general least squares problem defined by Eq. 2.4 and determine the inverse transform, $f(k, y)$.[25, 26] A direct solution to this problem can be obtained using methods such as singular value decomposition.[26] However these approaches generate solutions that are highly sensitive to the details of the noise and typically give many negative values for the parameters. Therefore approaches that allow constraint of the solution to positive values are desirable.

One of the most common methods for least-squares minimization is Levenberg-Marquardt (LM).[28, 29] This method is fast for small to medium sized data sets and is appropriate for both linear and non-linear models, but is subject to potential non-linear instabilities.[26, 30] A gridded representation of the kernel $A(k, t, y)$ is called a design matrix and eliminates non-linear instabilities because it allows the use of linear least squares algorithms like the Active-Set (AS) and the Interior-Point Gradient (IPG) methods.[31, 32] Though the setup is common in both methods, each minimizes the general least squares expression very differently.
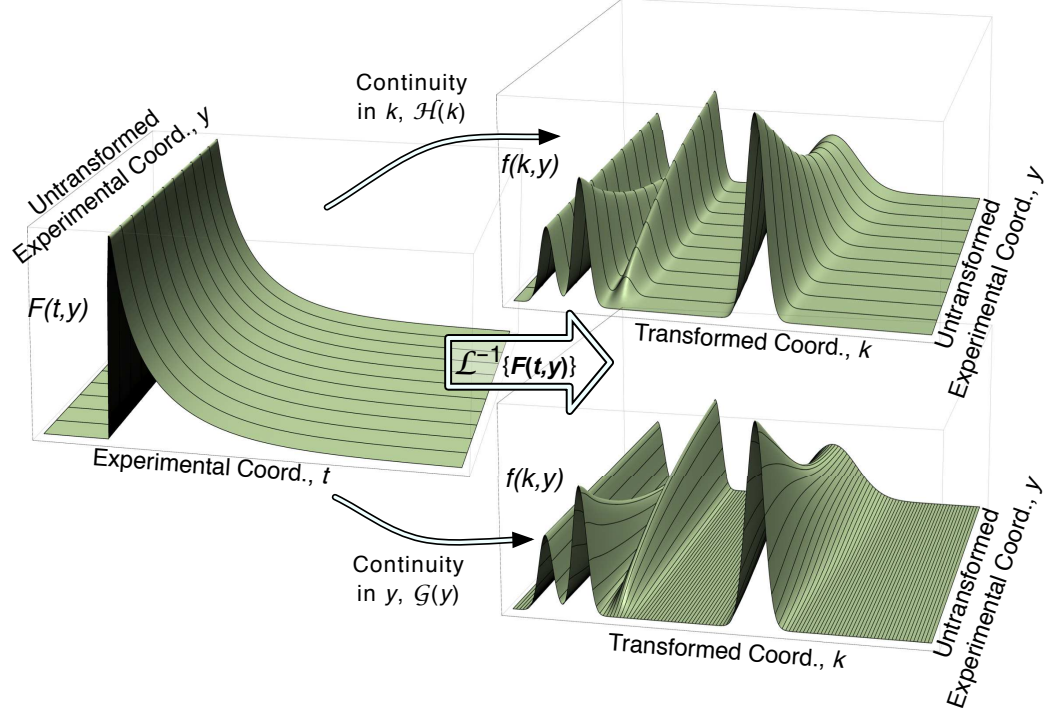

Figure 2.1: *Experimental prior knowledge* With global fitting available, prior knowledge in the form of a regularizer can either be be applied in the Laplace transform dimension, k, or in the experimental evolution dimension, y. In the left panel the individual data transients are indicated by the black mesh lines. In the right panels, the direction of continuity conditions is indicated by the black mesh lines. The top right panel emphasizes the continuity in the k dimension implying continuous distributions of properties. The bottom right panel emphasizes continuity in the y dimension implying continuous evolution of population.

The AS method enforces non-negativity on $f(k, y)$ by adding and removing basis functions from the kernel (design matrix).[31] This corresponds to expanding and contracting the dimensionality of that solution space, in effect finding the "right number" of exponentials on the grid to represent the fit. This method is computationally expensive for very large scale problems because of the continual matrix factorizations necessary to identify the active set. [33, 32]

The IPG method has an adaptive step size that accelerates convergence while limiting itself to steps that maintain the non-negativity of the solution at all points in the search, unlike the AS method.[32] IPG is a typical gradient method

in that it uses the entire set of basis functions and requires only matrix-vector multiplications.[34, 35] Though these methods are considered to be less accurate than the traditional AS method [32], the decreased convergence time of IPG for large problems makes it very useful. IPG accomplishes this by exploiting the totally non-negative structure of the problem to calculate this step and direction giving fits that converge faster than the classic Active-Set method.[32]

Because many different elements of the model space will give equally good fits to the noisy data,[30] all three methods we mention must constrain the model space, in some way, to stabilize the inverse Laplace transform. Since many of the solutions may not be physically reasonable, constraints can be selected based on prior knowledge. When $f(k, y)$ is a population then $f(k, y) \geq 0$. Instrumental limitations can limit the range of k that can be determined. When y is varied systematically then the global behavior of the individual species populations can be invoked to limit the possible $f(k, y)$. For example, the conservation of matter could provide a normalization condition for $f(k, y)$ at each value of y. The systematic variation of y could provide an expectation of a particular functional dependence of $f(k, y)$ along y for particular values of k representing different species. Limiting the model space with prior knowledge can be done with deterministic or probabilistic constraints.

Constraints of both types may be applied to the transformed variable, k, and the non-transformed variable, y. Constraints in the transformed variable are formed from hypotheses regarding the *nature of the system*, $f(k, y)$, across k. This is illustrated by the upper right panel of Fig. 2.1 where continuity has been invoked along k. Constraints in the non-transformed variable (such as time, temperature, solvent, etc.) require hypotheses that generate *global models* leading to specific functions or continuity conditions describing the *evolution of the system* across y. This is illustrated by the lower right panel of Fig. 2.1.

Deterministic constraints consider only some very small subset of functions

in the model space, and forbid all non-conforming solutions. Such empirical functions make the tacit prior assumption of a specific physical model for the system that gives analytical forms for $f(k, y)$ that transform trivially. A least-squares fit to $F(t, y)$ with these functions is equivalent to the inversion. The most common way is to use a small number (i.e. 1-3) exponential functions to fit the data. This limits the model space $f(k, y)$ to a small number of delta functions. All other possible solutions have their likelihood set to zero *a priori*. Global models are constructed by assigning specific functions to describe the evolution of $f(k, y)$ along y for all of the discrete values of k that represent a species. A drawback is that this can forbid the "true" solution from being obtained if it is not, by happenstance, consistent with the deterministic constraints.

By contrast, probabilistic constraints reduce the likelihood of solutions in proportion to their departure from the constraint, but do not set the likelihood of any solutions in the model space to zero. Probabilistic constraints are usually imposed by penalty functions or regularization conditions. The new fitting functional including regularization is,

$$\Xi^2 = \chi^2 + \gamma\Omega^2, \tag{2.5}$$

where χ^2 is the usual sum of the weighted squared residuals, Ω^2 is any arbitrary regularizer functional, and γ is the strength of the regularization.

Early work on probabilistic constraints[30, 17] used a second derivative regularizer functional of the form

$$\Omega^2 = \mathcal{H}(k) = \int \left[\frac{\partial^2 f(k, y)}{\partial k^2}\right]^2 dk \tag{2.6}$$

with the assumption that this would provide the most "parsimonious" discretized solution to the inversion problem.[17] This regularizer implies piece-wise linearity in k, strongly biasing against any discontinuities. There will be many systems for which this will not be valid, such as those having discrete distributions across k. Other regularizers have been used to probabilistically reduce the available

solution space for the inversion by imposing expectations of the nature of the solution in k.[36, 37]

Maximum entropy is another criterion that is often used as a regularizer [23, 36, 38, 39],

$$\mathcal{W} = \int \int f(k, y) - m(k, y) - f(k, y) \log\left(\frac{f(k, y)}{m(k, y)}\right) dk dy \qquad (2.7)$$

where $m(k, y)$ is the uniform distribution that gives maximum entropy. The entropy functional satisfies two conditions that serve to define it. Entropy is maximized for flat distributions. This has the physical meaning that all values of k are not only possible but equally likely. Entropy also has the property that it is maximized when, in a joint distribution, the likelihood is independent.[40, 16] That is, when $f(k, y) = f(k) \times f(y)$. This has the physical meaning that all species have identical behavior under the influence of the experimental variable. This is an excellent example of how assumptions about the behavior of the system can creep in without the explicit knowledge of the investigator. Also, since entropy is an extensive property, performing a maximum entropy analysis globally is identical to performing parallel local analyses, so long as the likelihood at each value of y is normalized across k. This suggests that though maximum entropy is a useful condition for probabilistic constraint of fitting, it is of limited benefit for global fitting in this context.

In this paper we introduce a method to exploit the global behavior of a system (e.g. continuity) across an experimental coordinate, y, to define a *global regularization condition* that does not make any assumptions about the shape or continuity in the Laplace transform dimension, k. In a typical experiment, k is directly related some property of the different species present and the concentrations of the different species change with the experimental coordinate, y, (e.g. over time by some kinetic rate law). Therefore the solution set, $f(k, y)$, will often be piece-wise continuous in y, implying smooth changes in the population of individual species with respect to y. To represent this behavior mathematically,

we introduce a global regularizer that favors solutions that satisfy the continuity/smoothness condition in y:

$$\mathcal{G}(y) = \int \left[\frac{\partial^2 f(k,y)}{\partial y^2} \right]^2 dy \qquad (2.8)$$

Implementation of Eq. 2.8 into Eq. 2.5 requires a general least-squares optimization algorithm that can accommodate the inclusion of a regularizer term. The IPG method minimizes Eq. 2.4 by choosing the scale of the step and direction to be as close as possible the exact minimizer *without* crossing into the non-negative region. We augment the IPG with a regularizer functional such that the step and direction favor solutions with continuity in the either the k, local, or y, global, dimensions.

To demonstrate utility of global regularization on an evolving data set, we simulate a test data set, evaluate fitting methods and compare and contrast existing method with methods introduced here. We also evaluate the effect of noise on each method's ability to reproduce the test parameter set. Lastly, we show how to use global regularization in the experimental domain with a traditional physical model for the species domain to do global fitting using LM.

2.3 Methods

2.3.1 IPG Regularizer

The computer implementation of Eq. 2.4 replaces continuous variables t, y, and k with discrete variables t_i, k_j, and y_l with $i \in \{1 \cdots T\}$, $j \in \{1 \cdots K\}$, and $l \in \{1 \cdots Y\}$. Matrix notation replaces continuous notation as follows. Each transient, $F(t, y_l)$ has a design matrix,

$$\mathbf{A}_l^{[T \times K]} \equiv A(t, k, y_l)/s(t, y_l),$$

a solution vector,

$$\mathbf{x}_l^{[K \times 1]} \equiv f(k, y_l),$$

and a data vector,

$$\mathbf{b}_l^{[T \times 1]} \equiv F(t, y_l)/s(t, y_l).$$

The design matrix and the data vector are scaled by the standard deviations of the data, which were estimated by $s(t, y_l) = \sqrt{F(t, y_l) + 1}$.

We momentarily drop the subscripts in our notation when considering one transient at a time. The minimum of Eq. 2.4 occurs when the derivatives with respect to the parameters equal zero, yielding the exact minimizing equation,

$$\mathbf{A}^T\mathbf{A}\mathbf{x} - \mathbf{A}^T\mathbf{b} = 0. \tag{2.9}$$

The details of the fitting algorithm can be found in [32]. The key feature of the algorithm is the way it determines the scaling vector for calculating each iteration:

$$\mathbf{d} = \frac{\mathbf{x}}{\mathbf{A}^T\mathbf{A}\mathbf{x}}. \tag{2.10}$$

Eq. 2.10 is the core of the IPG algorithm and makes it less sensitive to ill-conditioned problems. Ref. [32] shows that with condition number of $\mathbf{A}^T\mathbf{A} \approx 10^{16}$, the relative error of the fits between IPG and the Active-Set after 10^3 iterations is $\approx 10^{-5}$ and nearly five orders of magnitude better than other scaling methods. For our global fits, typical condition numbers range from 10^{18} to 10^{22} making the insensitivity of IPG to condition number particularly valuable.

Locally Regularized IPG

The same minimization principle can be applied when considering the cost function, Ξ^2 in (Eq. 2.5),

$$(\mathbf{A}^T\mathbf{A} + \gamma\mathbf{H})\mathbf{x} - \mathbf{A}^T\mathbf{b} = 0, \tag{2.11}$$

where the regularizer $\mathcal{H}$ is now represented as the regularization matrix $\mathbf{H}$.

$$\mathbf{H}^{[K \times K]} \equiv \begin{pmatrix} 1 & -2 & 1 & 0 & 0 & 0 & 0 & \cdots & 0 \\ -2 & 5 & -4 & 1 & 0 & 0 & 0 & \cdots & 0 \\ 1 & -4 & 6 & -4 & 1 & 0 & 0 & \cdots & 0 \\ 0 & 1 & -4 & 6 & -4 & 1 & 0 & \cdots & 0 \\ \vdots & & & & \ddots & & & & \vdots \\ 0 & \cdots & 0 & 1 & -4 & 6 & -4 & 1 & 0 \\ 0 & \cdots & 0 & 0 & 1 & -4 & 6 & -4 & 1 \\ 0 & \cdots & 0 & 0 & 0 & 1 & -4 & 5 & -2 \\ 0 & \cdots & 0 & 0 & 0 & 0 & 1 & -2 & 1 \end{pmatrix} \tag{2.12}$$

where, again K is the number of parameters for each transient. This second derivative regularizer matrix measures departure from piece-wise linearity in $f(k)$. Other regularizers will be appropriate depending on the available prior knowledge. Details for generating different types of regularization matrices are found in chapter 18-5 of reference [26]. For locally regularized IPG, we substitute $(\mathbf{A}^{\mathrm{T}}\mathbf{A} + \gamma\mathbf{H})$ for all occurrences of $\mathbf{A}^{\mathrm{T}}\mathbf{A}$ in the IPG algorithm.

Globally Regularized IPG

The global fits simultaneously consider all the available Y transients. Setting up globally regularized IPG is analogous to the locally regularized case, except that the entire data set is fit at once. The matrices and vectors must accommodate the global nature of the problem. This requires concatenation of local data transients and parameters into global vectors:

$$\mathbf{b} = \begin{pmatrix} \mathbf{b}_1 \\ \mathbf{b}_2 \\ \vdots \\ \mathbf{b}_Y \end{pmatrix} \text{ and } \mathbf{x} = \begin{pmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \vdots \\ \mathbf{x}_Y \end{pmatrix}. \tag{2.13}$$

The design matrices, $\mathbf{A}_l$ are placed in a block diagonal *global-design matrix,*

$$\mathbf{A} = \begin{pmatrix} \mathbf{A}_1 & 0 & \cdots & 0 \\ 0 & \mathbf{A}_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \mathbf{A}_Y \end{pmatrix}. \tag{2.14}$$

The regularization matrix is also expanded to incorparate continuity across the non-transformed dimension. Eq. 2.8 specifies a global regularization matrix, $\mathbf{G}^{[KY \times KY]}$. To obtain $\mathbf{G}^{[KY \times KY]}$, each element $(h_{1 \cdots Y, 1 \cdots Y})$ of Eq. 8.2, $(\mathbf{H}^{[Y \times Y]})$ is replaced by a $K \times K$ diagonal matrix:

$$\mathbf{G} = \begin{pmatrix} h_{1,1}\mathbf{I} & h_{1,2}\mathbf{I} & \cdots & h_{1,Y}\mathbf{I} \\ h_{2,1}\mathbf{I} & h_{2,2}\mathbf{I} & \cdots & h_{2,Y}\mathbf{I} \\ \vdots & & \ddots & \vdots \\ h_{Y,1}\mathbf{I} & h_{Y,2}\mathbf{I} & \cdots & h_{YY}\mathbf{I} \end{pmatrix}, \tag{2.15}$$

where $\mathbf{I}$ is a $K \times K$ identity matrix.

For global regularization, we substitute $(\mathbf{A}^T\mathbf{A} + \gamma\mathbf{G}) \rightarrow \mathbf{A}^T\mathbf{A}$ in the IPG algorithm.

2.3.2   Data Simulations

Ten $(Y = 10)$ time-correlated single-photon counting (TCSPC) measurements were synthesized with $T = 4096$ bins over 50 ns time-window range to evaluate the utility of the global regularization method. Each transient, $F(t, y_l)$, is generated by the matrix multiplication of an exponential decay matrix, $\mathbf{S}$ (with each element, $S_{ij} = exp(-k_j t_i)$) by a $K = 1200$ synthesized solution set (the exemplar) $\tilde{\mathbf{f}} = \tilde{f}(k, y_l)$. The synthesized solution set was evenly spaced in k^{-1}, from 0.01 to 12ns. The grid for the simulation was 10-fold denser than that used for the fit to better simulate the presence of continuous distributions.

The exemplar solution set, $\tilde{f}(k,y)$ was generated by representing four evolving species, each by a Gaussian distribution,

$$\tilde{f}(k,y) = \sum_{i=1}^{4} C_i \left(\sigma_i \sqrt{2\pi}\right)^{-1} e^{-\frac{1}{2}\left(\frac{k-k_i}{\sigma_i}\right)^2}. \tag{2.16}$$

Such fluorescence decay components commonly arise and are difficult to fit.[37, 41, 42, 36] Species **1** was centered at k_1^{-1}=7 ns, concentration C_1=1 and had an evolving width,

$$\sigma_1(y) = \left(0.2 + \frac{0.7}{e^{-(5-y)/2} + 1}\right) \text{ns}.$$

Species **2** (k_2^{-1}=2 ns, σ_2^{-1}=0.2 ns) has an initial concentration of C_2=0.5 and converts into Species **3** (k_3^{-1}=3 ns, σ_3^{-1}=0.2 ns) with a first order rate of 0.2/experimental unit in y. Species **4** was non-evolving in both k and y, (k_4^{-1}=1 ns, $\sigma_4^{-1} = 0.2$ ns) with constant concentration of C_4=0.3. The right two panels in Fig. 2.1 show the exemplar solution, $\tilde{f}(k,y)$, for the evolving test case, $F(t,y_l)$.

The intensity decays generated were convoluted with an instrument response function typical of microchannel plate photomultipliers.[43, 7] We examined the influence of noise on the fitting algorithms by generating data sets with different intensity levels. The peak convoluted decay intensities were scaled to eleven values: $\mathcal{I} = 10^2$, 2×10^2, 5×10^2, 10^3, 2×10^3, 5×10^3, 10^4, 2×10^4, 5×10^4, 10^5, and 10^8. We included uncorrelated background (e.g. dark counts) at an intensity level of 30 counts for every bin for all signal-to-noise (S:N) levels. The noise of photon counting was simulated from a Poisson distribution at the intensity of each bin in $F(t,y)$. For example, the case with an intensity of $\mathcal{I} \sim 10^4$ peak counts and 30 background counts has a S:N level of $\sim$100:1 at the peak.

2.3.3 Fitting Mechanics

All fits were performed with Igor Pro 6.01 (Wavemetrics Inc.) running on a 2.16 GHz Intel DuoCore MacBook Pro under Mac OS X 10.4 (Tiger) with 2 GB

of RAM. Active-Set and IPG were implemented as user-defined functions. Non-linear least squares fitting was performed implementing IGOR's Levenberg-Marquardt (LM) curvefit package.

Levenberg-Marquardt

We performed four types of exponential, instrument-response-convolved fits utilizing the LM method: three exponential model, four exponential model, global model and a regularized global model fit. For the global model fit, the entire data set was fit simultaneously. The global model was chosen based on the global IPG fits, the full rationale for which appears in the results.

Three and four exponential fits were of the form $F(t, y) = F_0(y) + \sum_{i=1}^{n} P_i(y)e^{-k_i t}$, where n = 3 or 4, respectively. All parameters F_0, P_i and k_i were unconstrained. The data were weighted by the estimated standard errors. Each data transient was fit individually. To provide the best likelihood of successful convergence, the initial guesses were determined from a successful multi-exponential fit for the high S:N limit ($\mathcal{I} = 10^8$). For each S:N ratio the initial guesses were scaled according to the intensity and used for the first transient. The resulting fit parameters were then used as the initial guess for the next transient in the data set. Convergence of the algorithm occurred when either the one of the two conditions were met: the number iterations reached a maximum of 100, or fractional decrease of sum of the weighted residuals, χ^2, from one iteration to the next was less than 0.001.

Global models were performed on an entire data set for a particular signal-to-noise ratio. The chosen model for the global fit was represented by one stretched exponential plus three exponentials:

$$F(t, y) = F_0(y) + P_1(y)e^{-\{k_1(y)t\}^{\beta(y)}} + \sum_{i=2}^{4} P_i(y)e^{-k_i t}, \qquad (2.17)$$

where k_2, k_3, and k_4 were global parameters and $\beta(y)$, $k_1(y)$, $P_2(y)$, $P_3(y)$, $P_4(y)$, and $F_0(y)$ were local. Initial guesses were determined using the same method as

the local fits. All parameters were constrained to be positive, and the following parameters were constrained by $0.8 < k_4^{-1} < 1.2$ ns, $1.5 < k_2^{-1} < 2.5$ ns, $2.8 < k_3^{-1} < 3.5$ ns, and $\beta \leq 1$. The rationale for the constraints is in the Results section. A perturbation coefficient applied to stabilize the estimates of the numerical derivatives calculated by LM and was necessary for a successful fit. In IGOR Pro, the coefficient is implemented via an "epsilon wave" and was set to 0.01. The convergence criteria were the same as the local LM fits.

The globally regularized model applies the second derivative global continuity condition on same local parameters across the non-transformed coordinate. The regularizer for any set of local parameters, $\mathbf{P}^{(Y \times 1)}$, is:

$$\Omega_P^2 = \mathbf{P}^T \mathbf{H} \mathbf{P} \tag{2.18}$$

where $\mathbf{H} \equiv \mathbf{H}^{(Y \times Y)}$ and $\mathbf{P} \equiv (local_1, local_2, ...local_Y)^T$. A regularizer value for any set of parameters can be calculated. For this paper, regularizer value for local parameters $P_1(y), P_2(y), P_3(y), P_4(y), k_1(y)$ and $\beta(y)$ were caluculated and summed into the total regularizer value for the model, Ω_M^2.

In order to use the same LM minimizer used to fit the three and four exponential fits, Igor's built in curve fitting operation was used to minimize the new cost function in Eq. 2.5. This was accomplished by expanding the data and fit by one data point (a total of $T \times Y + 1$ points). By placing the square root of $\gamma \Omega_M^2$ in the last fit point and a zero in the last data point, the fitting algorithm will add the squared the difference to the residuals giving the proper cost function.

Active-Set and Interior Point Gradient

AS and IPG require as input a design matrix $(\mathbf{A}_l)$, scaled data $(\mathbf{b}_l)$, and an initial guess for the solution $\mathbf{x}_l$. AS, IPG and locally regularized IPG fit each transient in a data set individually. For TCSPC data simulations in this paper the design matrix $\mathbf{A}$ has elements $\exp(-k_j t_i)$. The design matrix was convoluted

column-by-column with an instrument response function typical of microchannel plate photomultipliers. The total number of grid points per local fit was set to $K = 120$. The grid was evenly spaced in k^{-1} from 0.1 to 12.0 ns. For globally regularized IPG, these local matrices were organized as previously described in the methods for the global case.

The IPG method requires a scaling term $\lambda \in (0, 1)$ The scaling term is used when IPG attempts to take step into a non-feasible region of the parameter state space; λ is used to scale the maximum allowable step distance as to get close, but not reach the non-negative boundary. We set $\lambda = 0.9$ which is 90% of the largest step. In the current data fits λ was set to 0.9 because it seemed to converge the fastest while also avoiding local minima.

Convergence of the IPG algorithm was allowed a maximum of 10^6 iterations. Every 2000 iterations, χ^2 was evaluated. If the fractional decrease from one evaluation χ^2 to the next was less than 10^{-7}, the fit was considered converged. The high S:N limit data, $\mathcal{I} = 10^8$ required 10^7 iterations due to the large condition number of the global design matrix. Initial guesses were set to 10^{-32}.

We chose the linear continuity condition for both local regularization and for global regularization in Eq. 2.6 and 2.8, respectively. Adding the regularizer to the minimization for IPG modifies the condition needed to maintain the parameters in the non-negative region. To maintain the totally non-negative condition, regularized IPG requires $(\mathbf{A}^{\mathrm{T}}\mathbf{A} + \gamma\mathbf{H})\mathbf{x} > 0$, so γ is constrained by:

$$\gamma \leq \frac{\mathbf{Hx}}{\mathbf{A}^{\mathrm{T}}\mathbf{Ax}}. \tag{2.19}$$

For all S:N, γ was set many orders of magnitude below this maximum threshold.

Maximum Entropy method fits

Maximum Entropy fits were performed using a exponential rates and is minimized by the Levenberg-Marquardt method using the same convergence and constraint

criteria as described above. Each transient was fit locally using the the same design matrices, $\mathbf{A}_l$, as employed for the AS and IPG methods,

$$F(t, y_l) = \sum_{i=1}^{T} \sum_{j=1}^{K} A_{ijl} x_j l. \tag{2.20}$$

Maximum Entropy regularizer, $\gamma \mathcal{W}$, was by calculated using Eq.2.7 and were implemented using Igor's built in curve fitting operation in similar fashion as the global regularized model fits.

2.3.4 Model Similarity Criteria

Two perspectives can be taken to compare and contrast the fitting methods presented in this paper. The first compares the *quality of fit*, the second compares the *quality of parameters*. A model is considered acceptable when the quality-of-fit, χ^2, is below some statistcal threshold . Multiple acceptable models (usually differing in model simplicity) can be differentiated from each other via statistical testing. However, many models will be statistically indistinguishable based solely on quality of fit to the data, even when χ^2 is evaluated globally across all Y transients, frustrating the search for the "best" global model. The ultimate goal is to get the set of parameters that best represents the physics of the system assuming all candidate models give adequate fits to the data. We use the Kullback-Leibler divergence and species population deviation to evaluate the quality of the parameters as compared to the exemplar parameter set.

Quality-of-fit

The sum of the weighted, squared residuals, χ^2, is normally reduced by the expected variance or value of χ^2 based on normal statistics. However, because we have synthesized data, we can directly compare the true F(t,y) (i.e. noiseless data) to the noisy data to determine the actual variance of the data and reduce

the fit χ^2 by this value,

$$\chi_r^2 = \frac{\chi_{fit}^2}{\chi_{true}^2}. \tag{2.21}$$

χ_r^2 values are calculated for the entire data set. We consider an adequate fit to be $1.1 > \chi_r^2 > 1.0$. χ_r^2 with values above or below this range under-fitting or over-fitting the data, respectively.

The F-test is used to calculate the probability-to-reject the hypothesis that two fits are the same based on χ_r^2 [17]. Values close to 1 indicate the values of χ_r^2 are statistically different. For this paper, we use the F-test for two different purposes: to set convergence criteria and to compare the statistical significance of different model fits. The convergence criteria for IPG fits provided a probability-to-reject < 0.01 for all S:N when compared to the AS fits. The regularizer strength, γ, for local and globally regularized IPG fits was chosen such that probability-to-reject < 0.01 when compared to the AS fits. With very little regularization, we will show that even though fits are not statistically different, the underlying parameters distributions are. The F-test was used compare traditional global model fitting with regularized global fitting, again choosing the regularization strength such that probability-to-reject < 0.01. We also used the F-test to compare three exponential fit to the four exponential, traditional global fit and regularized global fits.

Quality-of-Parameters

Kullback-Leibler divergence is an information theory approach to quantify the difference between a "true" probability distribution and an arbitrary probability distribution, and represented by,

$$D_{KL} = \sum_k \sum_y f(k,y) \ln \left(\frac{f(k,y)}{\tilde{f}(k,y)} \right). \tag{2.22}$$

D_{KL} is a measure of the relative entropy of the two distributions. Perfect overlap of a test set would result in a value of $D_{KL} = 0$.

A common goal in fitting data is to determine the evolution of the populations of different species. Attribution of the populations from gridded fits such as the AS and IPG methods described above is not trivial. Therefore, we define regions of the grid that are attributed to each species. The region for each species is summed for a given value of y to determine the total population of that species. The evolution of species i in a particular data set was defined as $S_i(y)$:

$$S_i(y) = \sum_{k=k_{i,min}}^{k_{i,max}} f(k, y) \tag{2.23}$$

where $k_{i,min}$ and $k_{i,max}$ were set based on the features of the exemplar parameter set. Specifically, $k_{4,min}^{-1} = 0.6$ ns, $k_{4,max}^{-1} = 1.4$ ns, $k_{2,min}^{-1} = 1.5$ ns, $k_{2,max}^{-1} = 2.4$ ns, $k_{3,min}^{-1} = 2.5$ ns, $k_{3,max}^{-1} = 3.5$ ns and $k_{1,min}^{-1} = 5.0$ ns, $k_{1,max}^{-1} = 9.0$ ns. The species parameters are calculated for every S:N ratio, but we will only explicitly compare S_i's for different fitting methods at $\mathcal{I} = 10^4$.

An overall score for reproducing the populations over the evolution dimension y was determined by the mean-squared difference of the populations:

$$POP = \sum_{i=1}^{4} (\tilde{S}_i(y) - S_i(y))^2 \tag{2.24}$$

where $\tilde{S}_i(y)$ is the population vectors calculated from the exemplar model. This metric, along with the Kullback-Leibler divergence, alllowed us to score the overall performance of different methods for all S:N ratios in their ability to reproduce the underlying physics of the system.

2.3.5   Error Estimates

Parameter errors in ill-posed problems are unbounded.[17] This arises because many potentially very different parameter sets can fit the data equally-well. However for a particular fit one can estimate the errors in the parameters and the degree to which they are coupled from diagonal and off diagonal elements of the

covariance matrix, respectively. Taking the derivative of the Jacobian, Eq. 8.1, gives the Hessian matrix. The matrix inverse of the Hessian matrix gives the covariance matrix:

$$\mathbf{C} = ((\mathbf{A}^{\mathrm{T}}\mathbf{A} + \gamma\mathbf{H}))^{-1}. \tag{2.25}$$

The square root of the the diagonal elements of the covariance matrix provides an estimate of the errors in the parameters. Not all parameters will have a value of zero in the Jacobian given by Eq. 8.1. This is a consequence of the constraint of the paramters to be non-negative. These parameters are not active and should not be included in error estimates. Therefore, only parameters with values of the Jacobian that are close to zero should be included in the Hessian matrix. In our experience the covariance matrix gives large estimates for the errors in these ill-posed problems because of the large degree of anti-correlation between parameters.

2.4 Results

In this section we examine the results of several approaches to fitting the data generated by the exemplar model at different levels of photon counting noise.

2.4.1 Levenberg-Marquardt

A common method for multiexponential fitting of TCSPC data is non-linear least-squares optimization. This method implies a weighted sum of delta-functions at the different values of the decay rates in Laplace space. The number of delta-functions is static which helps to stabilize the inversion. Levenberg-Marquardt is one of the most common algorithms for accomplishing this. For the data sets generated by the exemplar model, less than three exponentials did not give satisfactory fits.
Figure 2.2: $f(k, y)$ *for three exponential fits.* Starting from top panel down: exemplar solution parameters, fit solution parameters synthesized with $\mathcal{I} = 10^5, 10^4, 10^3, 200$ peak mean photons. Superimposed numbers correspond to species described in Methods.

Three-Exponential Model Fits

Three exponential fitting was fast, robust, and relatively insensitive to initial guesses with respect to convergence, except for the high S:N limit ($\mathcal{I} = 10^8$) which converged much more slowly. Only at this high S:N limit did a fit yield a

value of χ_r^2 that indicated that the fit failed to reproduce the data. (See Fig. 2.11.)

Contour plots of the parameter values resulting from three exponential LM fits appear in Fig. 2.2. The discrete functions are unable to reproduce the width or evolution of Species **1** at any S:N. The conversion of Species **2** to Species **3** is never resolved. At high S:N ($\mathcal{I} \geq 10^5$) the conversion is represented by a single species with a decay rate at approximately the weighted average of the contributions of Species **2** and **3**. Species **4** should not evolve in either intensity or position and is only properly reproduced at high S:N ($\mathcal{I} \geq 10^5$).

The population evolutions for Species **1** - **4** at a moderate S:N, $\mathcal{I} = 10^4$, are compiled in Fig. 2.14. For this three exponential fit, $S_1(y)$, represented by brown circles, follows a similar trend to that of the exemplar evolution (shown by the solid line of the same color). $S_2(y)$ (green diamonds) is not present, suggesting the need for another exponential term. $S_3(y)$ (blue triangles) follows the correct increasing population evolution trend over the experiment coordinate, but is overestimated. $S_4(y)$ (red squares) decreases until it reaches the true population, $y = 2$, then flattens. The initial overestimation of Species **4** population evolution and total overestimation of Species **3** is a compensation for the inadequacy of the three exponential model to describe Species **2**.

Quantitative measure of the similarity (see D_{KL} and POP in Figs. 2.12 and 2.13, respectively) of the three exponential fit parameters and the exemplar model show little improvement with increasing S:N, even at the high limit ($\mathcal{I} = 10^8$). This is a consequence of the lack of flexibility in the model to represent the trends in the exemplar model. In effect, the correct model was excluded prior to fitting. A normal next step would be to add an additional exponential term to the model and compare the fits to the three exponential results.
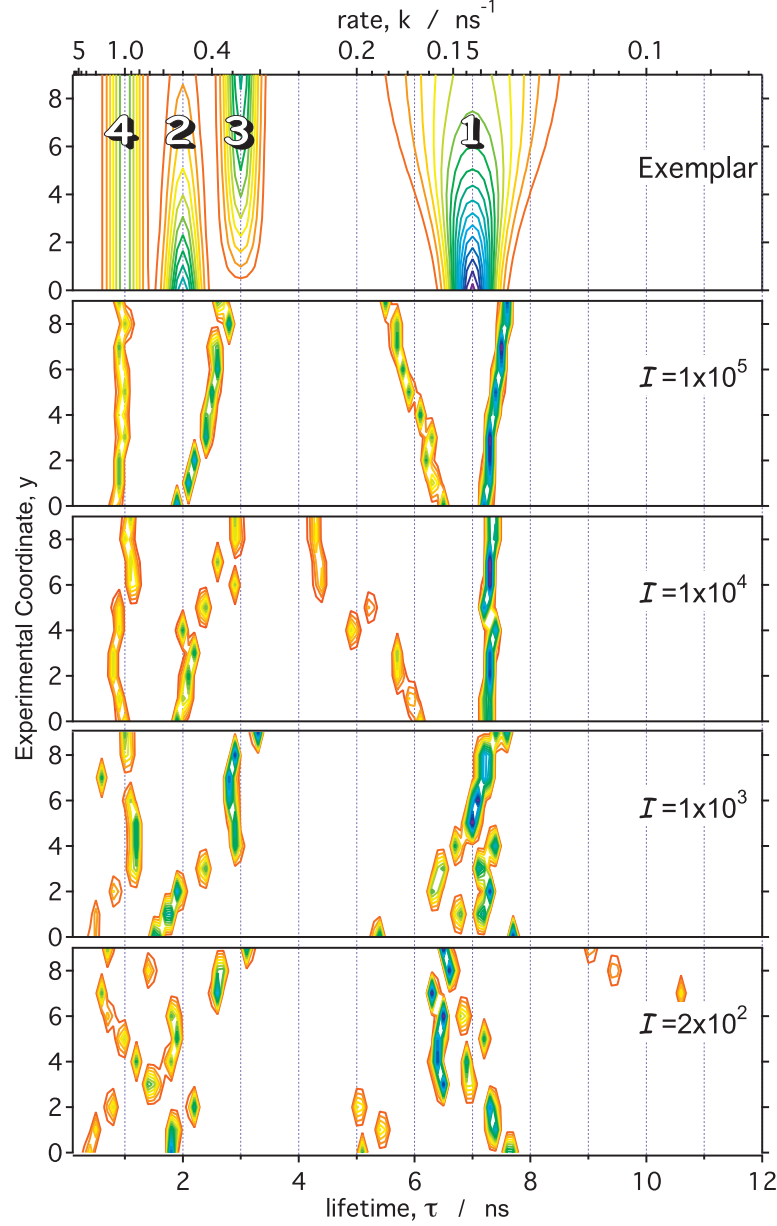

Figure 2.3: $f(k, y)$ *for four exponential fits.* Panels are described in figure 2.2.

Four-Exponential Model Fits

Contour plots of the parameter values resulting from four exponential LM fits appear in Fig. 2.3. For all S:N, the resulting parameters were sensitive to initial guesses, even though the χ^2 statistic was not. At the S:N limit ($\mathcal{I} = 10^8$), convergence became extremely sensitive to the initial guesses for the parameters. We note that this prompted our use of similar initial guesses for each S:N ratio

as described in the Methods. According to the F-test, the χ_r^2 values were not significantly different from those obtained for three exponential fits until high S:N (probability-to-reject for $\mathcal{I} \leq 2 \times 10^4$ was < 0.01). Only the high S:N limit ($\mathcal{I} = 10^8$) gave a value of χ_r^2 that indicated that the fit failed to reproduce the data. (See Fig. 2.11).

The four-exponential model fails to reproduce the exemplar model as illustrated in Fig.2.3. In the region of the distribution associated with Species **1**, the fit typically used two of the four available exponentials. There was no systematic trend in these components until high S:N ($\mathcal{I} \geq 10^5$) where the pair of exponentials are split and increases in separation over the non-transformed coordinate, y. Though this might have been hailed as a success, there is little to distinguish this pattern from that generated in the Species **2**, **3**, and **4** region. Here Species **4** is resolved, and the exchange of Species **2** and **3** is again reduced to a single exponential at the weighted mean.

These trends can be more clearly seen when we consider the species population evolutions in Fig. 2.14. The $S_1(y)$ decreases and diverges from the exemplar at $y = 6$ as the one of the two exponential rates, attempting to shape the edges of this distribution, overshifted to about $k^{-1} = 4.5$ ns. There was an abrupt exchange of population between $S_2(y)$ and $S_3(y)$ at $y = 6$ as the single exponential component shifts to longer lifetime. Finally, $S_4(y)$ evolved by first decreasing ($y \leq 5$) then, after a sharp increase, decreased again ($y > 6$).

The overall population overlap parameter, POP, was overall better than the three exponential fits and gradually, if inconsistently, trended toward improvement with increasing S:N. The Kullback-Liebler divergence also improved slightly with increasing S:N. Approaching the high S:N limit there was no further improvement in POP or in D_{KL}. Interestingly, χ_r^2 greatly deviated from one but was two orders of magnitude smaller than three exponential χ_r^2 at the same high S:N limit.

At low S:N the fits are of such poor stability that the addition of another

exponential makes it even more difficult to identify a trend in the fits, most likely because of the necessary trade-off between representing the different numbers of species and widths at the early versus late stages of the evolution across y. For example, in the first few transients, three species were being represented by four exponentials. Later there were four species active, but one of them required a width that needs at least a fifth exponential to represent it. All this would suggest that an adaptive method (such as the Active-Set method) that could change the number of exponential contributions as needed might provide better fits and better reconstruction of the exemplar model.

2.4.2 Active-Set

Contour plots of the parameter values resulting from Active-Set method fits appear in Fig. 2.4. The Active-Set method converged substantially slower than the three and four exponential LM fits. This difference became more pronounced with increasing S:N. The χ_r^2 steadily decreases with increasing S:N.

At low S:N, the fits are unstable and correct trends are difficult to ascertain. Species **1** is represented by two or three components, but no systematic trend appears. Likewise Species **2**, **3**, and **4** are represented by three or four components, but are not resolved until the high S:N limit ($\mathcal{I} = 10^8$ parameters not shown).

As can be seen in Fig. 2.4, the Active-Set method typically selects four to eight exponential contributions for a given position along the non-transformed (y) coordinate. However as can be seen in Fig. 2.11 this has not translated into a substantially better match with the exemplar; it is not only difficult to ascertain a trend for Species **2**, **3** or **4** at any S:N, but there is little evidence of distribution of rates for Species **1**.

The lack of any discernible trend has translated into erratic behavior of the species evolutions in Fig. 2.14. Again, $S_1(y)$ slowly deviates from the exemplar as the width of the distribution of Species **1** increases. Populations $S_2(y)$ and $S_3(y)$
Figure 2.4: $f(k, y)$ *for Active-Set Method fits.* Panels are described in figure 2.2.

randomly exchange across the experimental coordinate while S_1 fluctuates about exemplar population values.

Though performed on a grid, the Active-Set method tends to give discrete distributions. This is a consequence of the algorithm used to expand and contract the basis set. During the search for the best fit the algorithm explores regions of parameter space that include negative populations. To correct for this, these

negative values are pruned from the active set of basis functions. It is usually the closely-related basis functions that get pruned. This results in the suppression of solutions with continuous distributions. This tends to make Active-Set method not fit distributions as well as one might expect given that the distribution is explicitly allowed by virtue of the procedure being performed on a grid.

2.4.3 Maximum Entropy Method

A commonly used method to improve the stability of multi-exponential and distribution-of-exponentials fitting is to regularize using maximum entropy (MEM). The parameter values of the resulting fits are shown in Fig. 2.5. The MEM converged substantially slower than the Active-Set fits. Good fits were only obtainable when the regularizer parameter was increased to a value consistent with a ten-fold higher probability-to-reject the regularized solution as compared to the typical IPG regularized fits (*vide infra*). The χ^2_r steadily decreases with increasing S:N and displayed a consistent trend with AS fits even at the highest S:N.

At low S:N ($\mathcal{I} = 2 \times 10^2$), none of the species are resolvable. At modest S:N ($\mathcal{I} = 10^3$) the distribution of Species **1** is apparent and is the first example in this paper of fitting method depicting a distribution. Though Species **1** distribution becomes better defined as high S:N, Species **2**, **3**, and **4** are still undecipherable. Only in the high S:N limit ($\mathcal{I} \leq 10^8$) are all the species resolvable.

Kullback-Liebler divergence and the overall population parameter, POP, systematically improves with increasing S:N. At (unrealistically) high S:N limit, these parameters are extremely good.

2.4.4 Interior Point Gradient Method

The Interior Point Gradient method improves the grid-based solution by performing the fit search in such a way that physically forbidden (negative population)
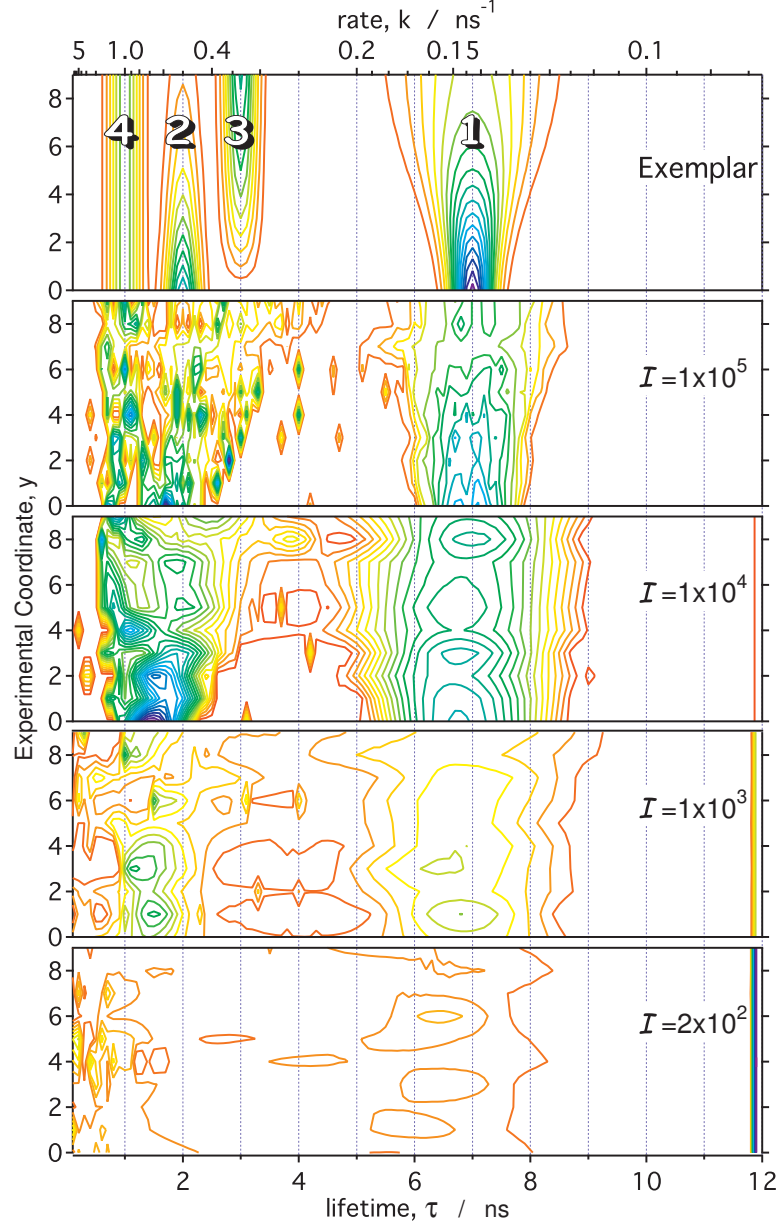

Figure 2.5: $f(k, y)$ *for MEM fits.* Panels are described in figure 2.2.

values of the parameters are never accessed. Execution time of the algorithm was substantially faster than that of the Active-Set method, but slower than LM. Adding local regularization to IPG increased the average iteration time by less than 10%. globally regularized IPG was the slowest to converge because this method fits all the data simultaneously. For all reasonable values of S:N ($\mathcal{I} \leq 10^5$) the resulting χ_r^2 were consistent with a good fit as seen in Fig. 2.11.
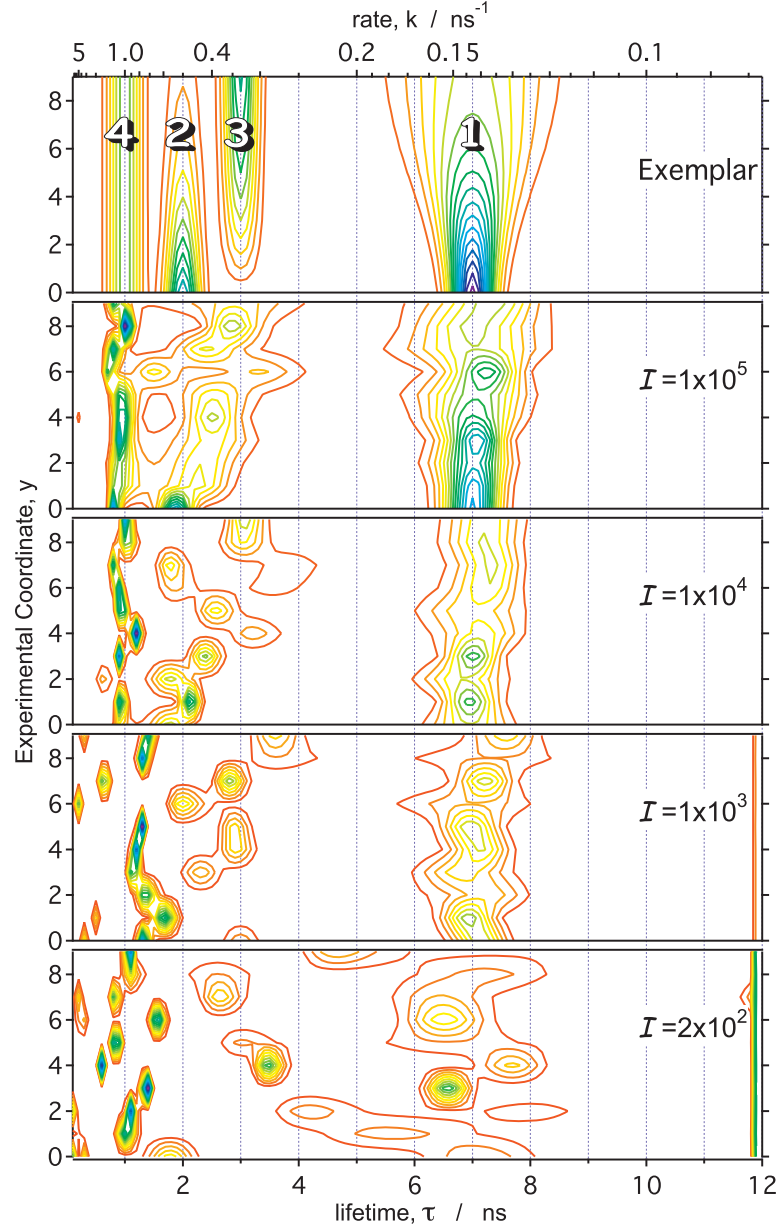

Figure 2.6: $f(k, y)$ *for IPG fits.* Panels are described in figure 2.2.

Unregularized IPG

Contour plots of the parameter values resulting from unregularized IPG fits appear in Fig. 2.6. The IPG fits do a better job reproducing distributions, such as that of Species **1**. Even at modest S:N ($\mathcal{I} \geq 10^3$) the distribution of Species **1** is well defined, though the proper evolution of its width is not resolved except for high S:N ($\mathcal{I} \geq 10^5$). The contributions of Species **2**, **3**, and **4** are unstable at low

S:N.

At high S:N ($\mathcal{I} = 10^5$) Species **4** is resolved from Species **2** and **3**. However, the conversion of Species **2** to **3** is a shifting distribution rather than separate exchanging distributions. Only at the high S:N limit ($\mathcal{I} = 10^8$ parameters not shown) does the unregularized IPG method reproduce the contributions from all four species and their evolution with y.

Even though population distributions are being reproduced, the species populations for the IPG method evolve erratically over the experiment coordinate. $S_1(y)$ decreases with y but the deviation from the exemplar, $\tilde{S}_1$, is less than seen in AS. $S_2(y)$ and $S_3(y)$ readily exchange population. $S_4(y)$ is far from constant evolution across y.

Kullback-Liebler divergence systematically improves with increasing S:N. The overall population parameter, POP, also improves with increasing S:N. Fitting data with high S:N, $\mathcal{I} \geq 2 \times 10^4$, there is a big improvement in POP. Comparing parameters in Fig. 2.6 with moderately-high to high S:N, i.e. $\mathcal{I} = 10^4$ to $\mathcal{I} = 10^5$, IPG gains the ability to separate Species **2** from Species **3**, albeit, with minimal, success. To improve the IPG's inability to accurately reproduce parameters at low S:N, a regularizer may be used to stabilize the fitting procedure.

Locally Regularized IPG

The effect of the local regularizer on the fits can be seen in Fig. 2.7 as effectively broadening the distributions as compared to unregularized IPG. The imposition of the continuity condition in the transformed dimension k has essentially given very similar solutions to that of the unmodified IPG except that the distributions have broadened beyond the exemplar widths. At very low S:N, the correct trend is impossible to ascertain in any reasonable way. Fitting moderate S:N data ($\mathcal{I} = 10^4$), the distribution of Species **1** is resolved but does not correctly evolve in width. Concurrently, Species **2**, **3** and **4** are merged into an undecipherable
Figure 2.7: $f(k, y)$ *for Locally Regularized IPG fits.* Panels are described in figure 2.2.

single species. At high S:N ($\mathcal{I} = 10^5$), Species **1** is resolved with a similar width evolution as the exemplar. However, for $y < 4$ Species **2**, **3**, and **4** are merged making it difficult to establish initial species. Even at this S:N, Species **1** has been over-estimated in width.

The species populations for locally regularized IPG were far more stable than

the AS or unregularized IPG. $S_1(y)$ decreased away from the exemplar population after $y = 6$. Even though the distributions of Species **2** and **3** were unresolved, the evolution of $S_2(y)$ and $S_3(y)$ indicated that the correct populations were beginning to be recovered, though they were still unstable. There was an apparent trend of decrease in population of Species **2** and a simultaneous increase in Species **3**. $S_4(y)$ was well-behaved about its correct exemplar value.

Though the qualitative trends comparing the locally regularized IPG fit parameters to the exemplar model suggested worse fits, the Kullback-Liebler divergence was smaller than the unregularized case. This is a result of broader distributions being more forgiving in terms of overlap with the exemplar model. Even the population is slightly better-reproduced in the locally regularized IPG fits. Similar to the unregularized case there is a big improvement in this metric occuring at low S:N, $\mathcal{I} = 2 \times 10^3$ to $\mathcal{I} = 10^4$. As seen in Fig. 2.7, Species **1** becomes better defined at higher S:N, as well as separating Species **3** from Species **1** for $y \geq 7$.

Overall, the regularization of IPG stabilized the solution set and may allow the investigator to establish trends at high S:N. Though the evolution of species populations showed reasonable overlap with the exemplar in Fig. 2.14, it is unlikely that that local regularization would lead the investigator to correctly identify the number and properties of species present.

Globally Regularized IPG

The globally regularized IPG method was far superior for reproducing the exemplar model. Even at level of S:N appropriate for a single molecule measurement, $(\mathcal{I} = 2 \times 10^2)$ the fit demonstrates that the long lifetime species was a broad distribution whereas the short lifetime components were narrower. Species **1** broadens with y. The presence and conversion of Species **2** and **3** were beginning to be
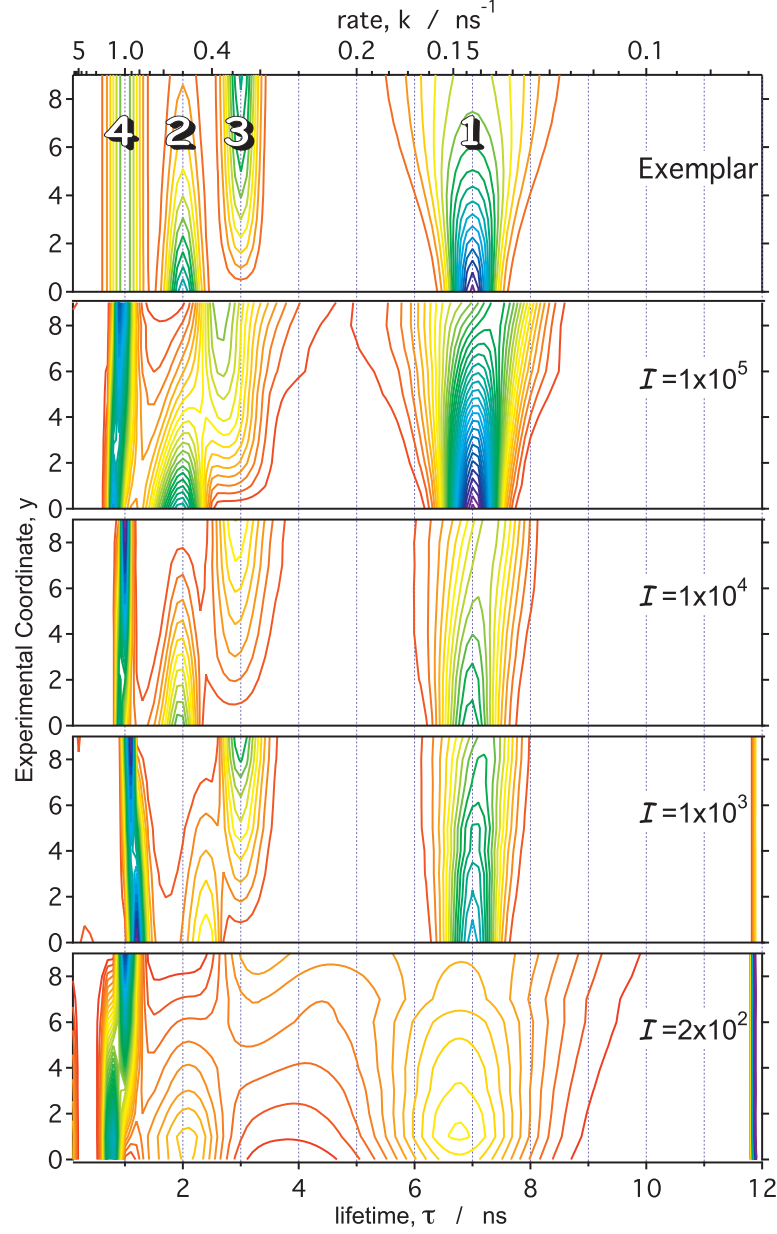

Figure 2.8: *f(k, y) for Globally Regularized IPG fits.* Panels are described in figure 2.2.

resolved. At modest S:N ($\mathcal{I} = 10^3$), Species **2** and Species **3** were clearly two separate populations converting from one to the other, adjacent to a third constant Species **4**. The mean of the population distribution of Species **1** was about 7 ns, increasing in width along the experimental coordinate.

The species population evolution was quite similar to that of the exemplar.

Species populations $S_2(y)$ and $S_3(y)$ both slowly exchanged populations without affecting $S_4(y)$. Notice that populations followed a more linear trend than the exemplar populations for Species **2** and **3**. This was due to the linear nature of the regularization condition applied in the fitting algorithm.

The quality-of-fit improved systematically with increasing S:N. The quality-of-parameters also became increasing better with S:N. POP decreases abruptly between $\mathcal{I} = 10^2$ and $\mathcal{I} = 2 \times 10^2$, then again between $\mathcal{I} = 5 \times 10^3$ and $\mathcal{I} = 10^4$. Though the globally regularized IPG method reproduced a distribution for Species **1**, at the lowest S:N there was an inability to distinguish between Species **2**, **3**, and **4** (data not shown). At slightly higher S:N, this was no longer a problem. When comparing moderate to high S:N, not only were the Species **2** and **3** better separated, their populations more closely matched the exemplar. This represented the second drop in POP. The Kullback-Liebler divergence also steadily decreased with increasing S:N. Fits for data with low to modest S:N, $\mathcal{I} = 5 \times 10^2$ to $\mathcal{I} = 10^3$, also showed a drop in the divergence parameter. This small increase in S:N allowed the globally regularized IPG method to clearly define all species and populations.

The globally regularized IPG fitting procedure does a great job reproducing the evolution of the exemplar model. However the exact evolution of the population of the species present must be interpreted by extracting them from the gridded fits. Moreover there is no way of directly interpreting the physics or chemistry implied by the evolution from these fits. This is the consequence of the probabilistic constraints as opposed to specifying a particular physical model. The advantage is that since models were not eliminated *a priori*, one can use the globally regularized IPG fits to determine an appropriate physical model for traditional global fitting as appears in the next subsection.

2.4.5 Global Model LM

A global model puts deterministic constraints on the model space in the transformed coordinate. We determined a global fitting model using the distribution of rates from the globally regularized IPG fit at $\mathcal{I} = 10^4$ in Fig. 2.8. From this fit, it is clear that there are four species. Species **1** had a significant width, that slightly evolved and was centered at k^{-1}= 7 ns. Conventional global fitting might treat this as a stretched exponential expression (second term in Eq. 2.17) in order to model a distribution of rates. Both the stretch parameter, $\beta(y)$ and the rate parameter, $k_1(y)$ must be local parameters since $\beta(y)$ changes not only the width of the distribution but also the mean.

The global fit also showed that Species **2**, **3** and **4** were fairly narrow distributions thus represented by single exponentials, each with global rates, k_2, k_3 and k_4. Though the populations of these species had fairly consistent trends (i.e. Species **2** descended, **3** ascended and **4** remained nearly a constant in amplitude) the model was kept general enough to allow variability in populations across the evolution, by employing local pre-exponential factors $P_2(y)$, $P_3(y)$, $P_4(y)$, respectively. The fit model also contained a baseline term, $F_0(y)$, local for each data transient.

Part of the instability of non-linear least-squares fitting of multi-exponential functions arises from the lack of constraints on the the exponential parameters. Even with the proper discrete global model, the fit procedure must be constrained. If they are left unconstrained, the exponential parameters can attain the same values. When this occurs, singular matrix errors are encountered by the LM algorithm causing the fit to fail. To forbid the global rate parameters from combining, a problem common with non-linear multi-exponential fitting, constraints were used. Constraints were placed upon global parameters, k_2, k_3, and k_4, and they were chosen based on the trends in the $\mathcal{I} = 10^4$ globally regularized fits.
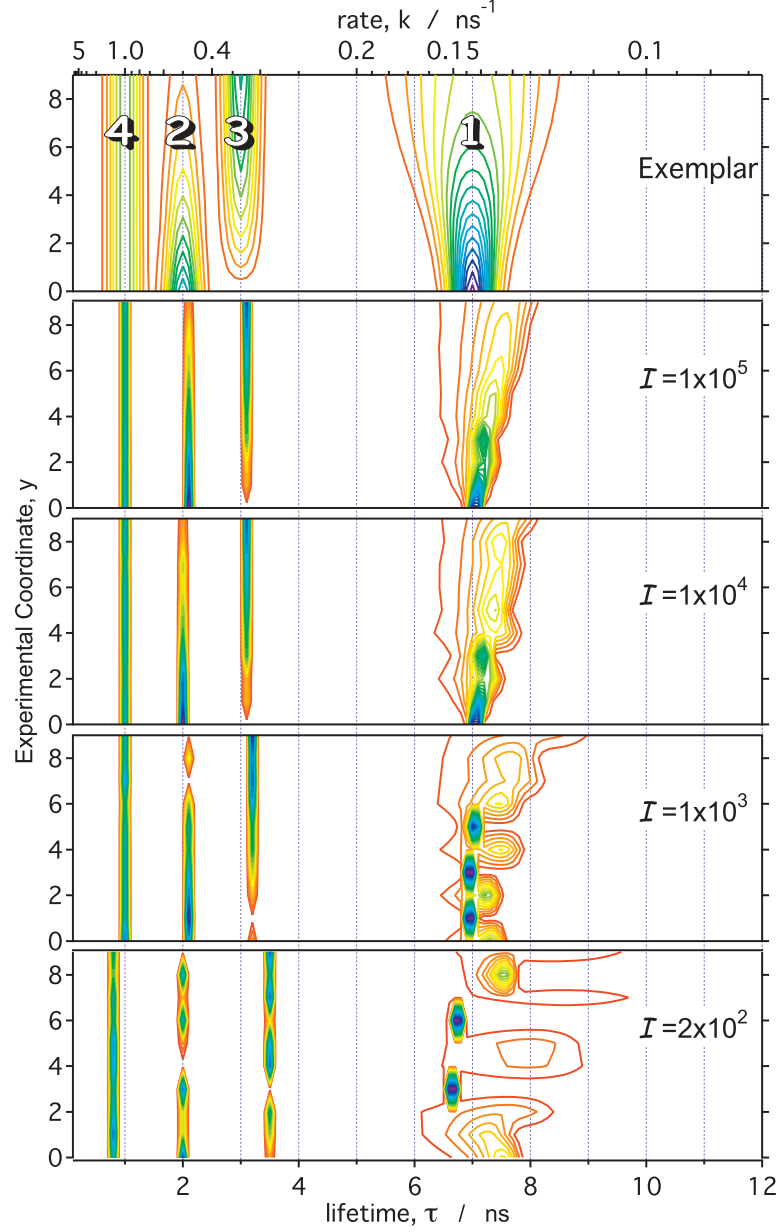

Figure 2.9: $f(k, y)$ *for Global Model fits.* Panels are described in figure 2.2.

Traditional Global Model LM

For all reasonable S:N levels ($\mathcal{I} \leq 10^5$), good fits were obtained as determined from χ_r^2. In fact, there was no significant statistical difference in quality-of-fit across nearly all S:N levels $\mathcal{I} \leq 5 \times 10^4$, comparing the three exponential model and the stretched model (Probability-to-reject ≤ 0.01). At high S:N limit $\mathcal{I} = 10^8$ the χ_r^2 value increased suggesting that the discretization of the model was beginning

to make a difference in the quality of the fit at that limit. For all S:N, fits were robust but at low S:N, $\mathcal{I} \leq 2 \times 10^2$, the global rates were often limited by the constraint (not all data is shown).

For the low S:N fits, the stretched exponential term was not able to consistently reproduce the Species **1** distribution. The $\beta(y)$ parameter converged to 1 in several cases resulting in a discrete exponential for some values of y. Even though Species **1, 2** and **3** were centered at nearly the correct lifetime, the local amplitudes fluctuate greatly at low S:N. By a moderate S:N level, $\mathcal{I} = 10^4$, the fits nicely reproduce the width and evolution of the Species **1** distribution. The instability of the β parameter for the fit to Species **1** appeared to interfere with the fitting of the conversion of Species **2** to **3**, which was not correctly reproduced until $\mathcal{I} = 10^4$. The Species **4** region was properly reproduced even at low S:N, $\mathcal{I} = 2 \times 10^2$.

As anticipated, the ability of the global model to reproduce the populations was excellent. The populations trends appeared to be only slightly "noisy" across y. Moreover, the POP metric shows global model thus far producing the best overlap with each species population from $\mathcal{I} \geq 5 \times 10^2$. Because all population for a particular species were determined from subranges of the grid of k's, the POP parameter was less sensitive to the discrete nature of model used to describe Species **2**, **3** and **4**. The plateau in D_{KL} divergence at $\mathcal{I} \sim 10^4$ suggests that above this value the deterministic constraints on the transformed coordinate dimensions of the model space limit the quality of overlap with the exemplar model.

The local nature of the amplitude parameters allowed them to fluctuate greatly along y, especially for low to modest S:N. A specific deterministic model along y related to some physical theory could help stabilize this situation. We note that since there was no improvement in Kullback-Liebler divergence or POP for high S:N limit ($\mathcal{I} = 10^8$), we expect little gain in parameter stability at moderately high S:N ($\mathcal{I} > 10^4$) with a regularized model. Nonetheless, in the spirit of first
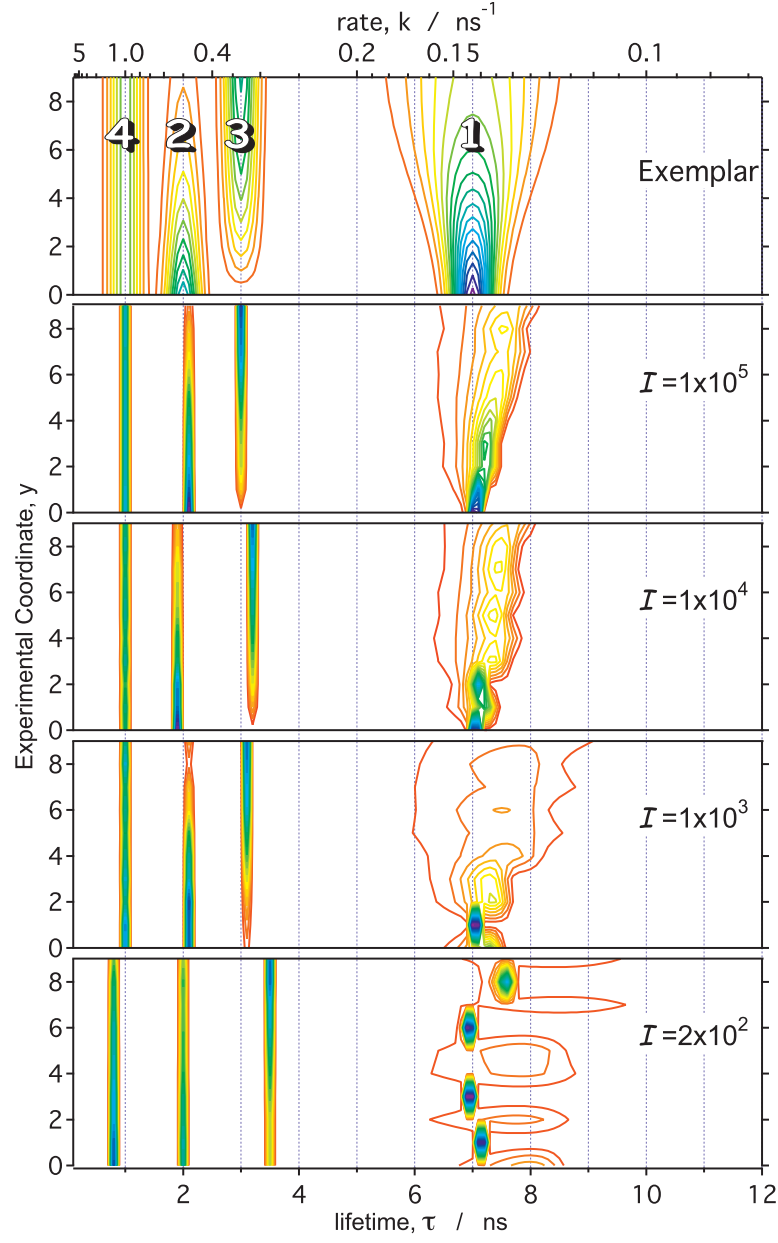

Figure 2.10: *f(k, y) for Regularized Global Model fits.* Panels are described in Fig. 2.2.

using probabilistic models, we attempted to regularize the model fit along the y coordinate as a way to use global information without a specific model.

Regularized Global Model LM

Regularization of the global LM fitting increased convergence time by no more than a factor of 2 and increased the stability of the fitting procedure. The values of χ_r^2 indicated good fits across all reasonable values S:N and were not statistically different from the traditional global model fits as measured by the F-test (probability-to-reject < 0.05).

The addition of the regularizer stabilizes the distribution due to Species **1**. This, in turn, stabilized the evolution of Species **2** and **3** since Species **1** was no longer interfering with them. Overall good fits were obtained at moderate S:N $\mathcal{I} \geq 10^3$.

The globally regularized model fit was a considerably better method for reproducing the distribution of Species **1** at very low S:N. Species **1** had a clear distribution across the experimental coordinate, but lacked an evolving trend in width. Species **2**, **3** and **4** had the correct population trends but are close to the employed bounds. For data with $\mathcal{I} \geq 10^3$, all species were well within the imposed bounds, while showing an evolving width associated with Species **1**. The ability of this method to resolve Species **2**, **3** and **4** did not change much with increasing S:N $\mathcal{I} \geq 10^3$, while Species **1** improved with better S:N.

The addition of the regularizer to an otherwise traditional global fit improved the ability of the fit to reproduce systematic changes in species population evolution as seen in Fig. 2.14. Specifically, the evolutions for the regularized global model were noticeably smoother. As with the globally regularized IPG fits, $S_2(y)$ and $S_3(y)$ were more linear than their respective exemplar evolutions. The constant species, $S_4(y)$, also did not have a consistent increasing trend, as it did for the globally regularized IPG. Though $S_1(y)$ was slightly overestimated, the population evolution was nearly constant.

The match with the exemplar model was limited because of the discrete character of the model in the transformed dimension as seen in the Kullback-Liebler divergence. However, when comparing the Kullback-Liebler divergence for the regularized global model fits to the traditional global model, the regularizer model reached a plateau sooner ($\mathcal{I} = 10^3$ versus $\mathcal{I} = 5 \times 10^3$). As seen in Fig. 2.9 and Fig. 2.10, the regularized global model stabilized the evolving distribution of Species **1** with modest S:N, $\mathcal{I} = 10^3$. There was no improvement in Kullback-Liebler divergence in the high S:N limit($\mathcal{I} = 10^8$).

The POP metric steadily decreased until a plateau was reached for moderate S:N, $\mathcal{I} = 2 \times 10^3$. This indicated that from a species population point-of-view, nothing else can be gained from better S:N. This can be seen in the increase in the POP value for fits to the highest S:N data ($\mathcal{I} = 10^8$), thereby showing the addition of a regularizer is not necessary for a discrete global model fit to virtually infinite S:N data.

2.5   Discussion

2.5.1   Comparison of Methods

In the results we evaluated how the S:N ratio influenced the success of each fitting method using χ_r^2, the Kullback-Liebler divergence, and the population parameters. We now compare the different methods to each other and discuss why they gave different results.

Reduced Chi-square

The four deterministically constrained models (all optimized with LM) showed little systematic change in χ_r^2 until $\mathcal{I} \geq 5 \times 10^4$, at which point χ_r^2 began to get worse. By comparison, the gridded methods (optimized by AS, MEM, or IPG) showed steady improvement in χ_r^2 until $\mathcal{I} = 10^5$. There was no statistical

difference of fit between the AS fit and any of the MEM or IPG fits except in the high S:N limit ($\mathcal{I} = 10^8$). The MEM fits gave slightly higher χ_r^2 because of the higher value of the regularizer strength parameter required to get reasonable fits. One interpretation of the higher χ_r^2 for the gridded methods would be that they were done on too coarse of a grid. However, the improvement in χ_r^2 with increasing S:N suggests otherwise, since a constraint in the model space would be reflected as a lower boundary for the χ_r^2. Furthermore, improving the grid resolution did not change χ_r^2. Grid methods have more model flexibility and can take advantage of the increased S:N, however the model space they are performed in does not include terms that adapt to the noise.

The global model fits were not statistically different than the three exponential fits until they began to diverge in terms of χ_r^2 at $\mathcal{I} > 10^4$ because they have less model flexibility than three exponential and four exponential fits. According to χ_r^2 the three exponential model was adequate to describe the data for these fits until high S:N. In the high S:N limit it was quite clear that neither the three nor the four exponential fit was a good model for the system.

Kullback-Liebler divergence

The Kullback-Liebler divergences comparing the exemplar parameters to the three exponential, four exponential, AS, global model and regularized global model fits did not improve much with increasing signal-to-noise. (See Fig. 2.12) The deterministic constraints implied by these fitting methods forbid the true solution.

At low S:N ($\mathcal{I} = 10^2$) the methods were all clustered. In this limit the AS method was worst and the three exponential model was best. This suggests that too much model flexibility is not good when the there is little information in the data, as the model flexibility will be used to fit noise. The MEM and IPG methods did a better job than AS because they tended to give continuous distributions that better represented the broad part of Species **1** and were less able to adapt
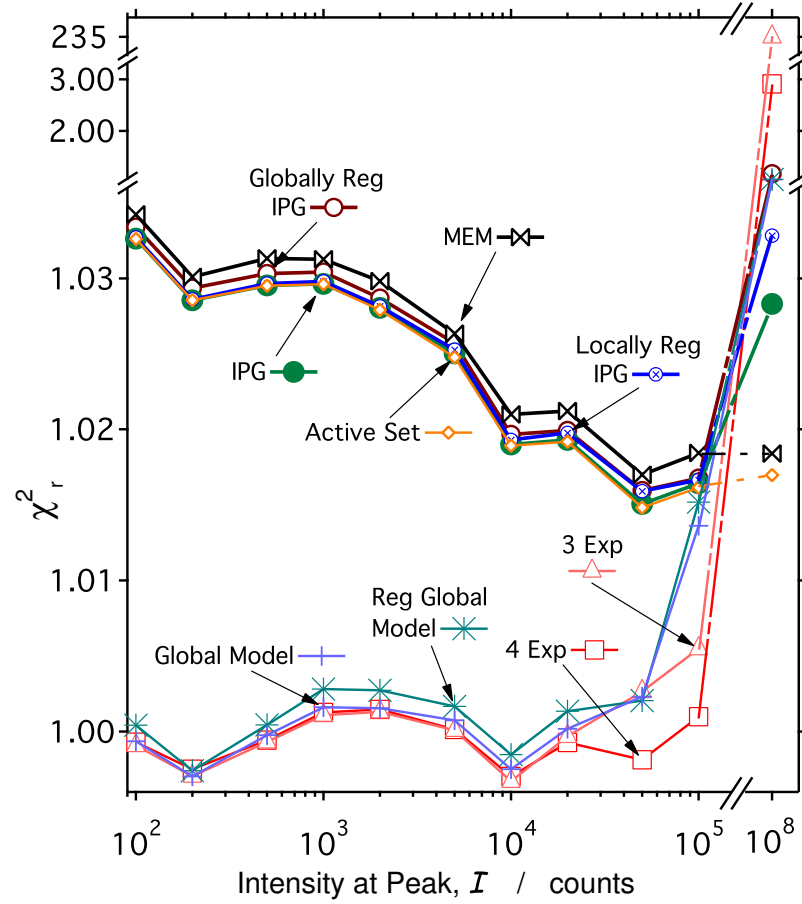

Figure 2.11: χ_r^2 *for all* $\mathcal{I}$ *using different fitting methods.* ($\triangle$)–Three Exponential fits, ($\square$)–Four Exponential fits, ($\diamond$)–Active-Set Method fits, ($\bowtie$)–Maximum Entropy Method fits, ($\bullet$)–IPG fits, ($\otimes$)–Locally Regularized IPG fits, ($\circ$)–Globally Regularized IPG fits, ($+$)–Global Model fits, ($*$)–Regularized Global Model fits.

to fit details of the noise.

With a modest increase in S:N ($\mathcal{I} = 10^3$) the IPG and global models all showed a lower divergence from the exemplar model than did the three and four exponential, MEM, and AS method. This was primarily a consequence of their ability to represent the width of Species **1**. The MEM fits continued to improve, however, not as quickly as the IPG and global-model methods. The Kullback-Liebler divergence for the three and four exponential and AS methods reached a plateau here; they could not improve because the model was fixed, and they could
Figure 2.12: *Kullback-Liebler divergence* from the exemplar model versus $\mathcal{I}$ using the different fitting methods. Fitting methods are represented in the same markers as in Fig. 2.11.

not take advantage of the increased information available at higher S:N. Multi-exponential fitting optimizes the exponential parameters after assuming the size of the solution space is drastically limited. Multi-exponential fitting never considers solutions of the form that IPG uses to find a best fit. In the case of the AS method, the fitting algorithm is such that it chooses multiple-discrete representations of the distribution of Species **1**. AS disfavors smooth distributions since they include more basis functions and usually give negative values in the matrix factorization step of the algorithm. The fundamental problem with the AS method is that in its search it allows intermediate solutions that have non-physical negative amplitudes and deletes basis functions to prevent the negative amplitudes from being realized, but in the process also eliminates possible correct solutions. This tends to split smooth distributions into multiple discrete components. As a result AS chooses what could be considered a minimal entropy solution.
Figure 2.13: *POP for all $\mathcal{I}$ using different fitting methods.* Fitting methods are represented in the same markers as in Fig. 2.11.

By $\mathcal{I} \geq 2 \times 10^3$ all the IPG methods are better than the global model fits. This is because the global model fits are representing the narrow width of each of the Species **2**, **3**, and **4** by discrete exponentials. This restriction on the model space resulted in a limitation of how well it could reproduce the exemplar model. Rather than adjusting the fit model to include a width, as in the IPG methods, the differences between a discrete versus a narrow distribution were compensated by minor adjustments of other parameters and do not greatly affect χ_r^2.

Across the range of $10^3 \leq \mathcal{I} \leq 10^5$ the globally regularized IPG fitting was superior to the other methods. This is because the regularizer favors those solutions that are continuous in y, resulting in better overlap with the exemplar parameters. IPG evolves the fit distribution within the full solution space until the distribution reaches a best fit.
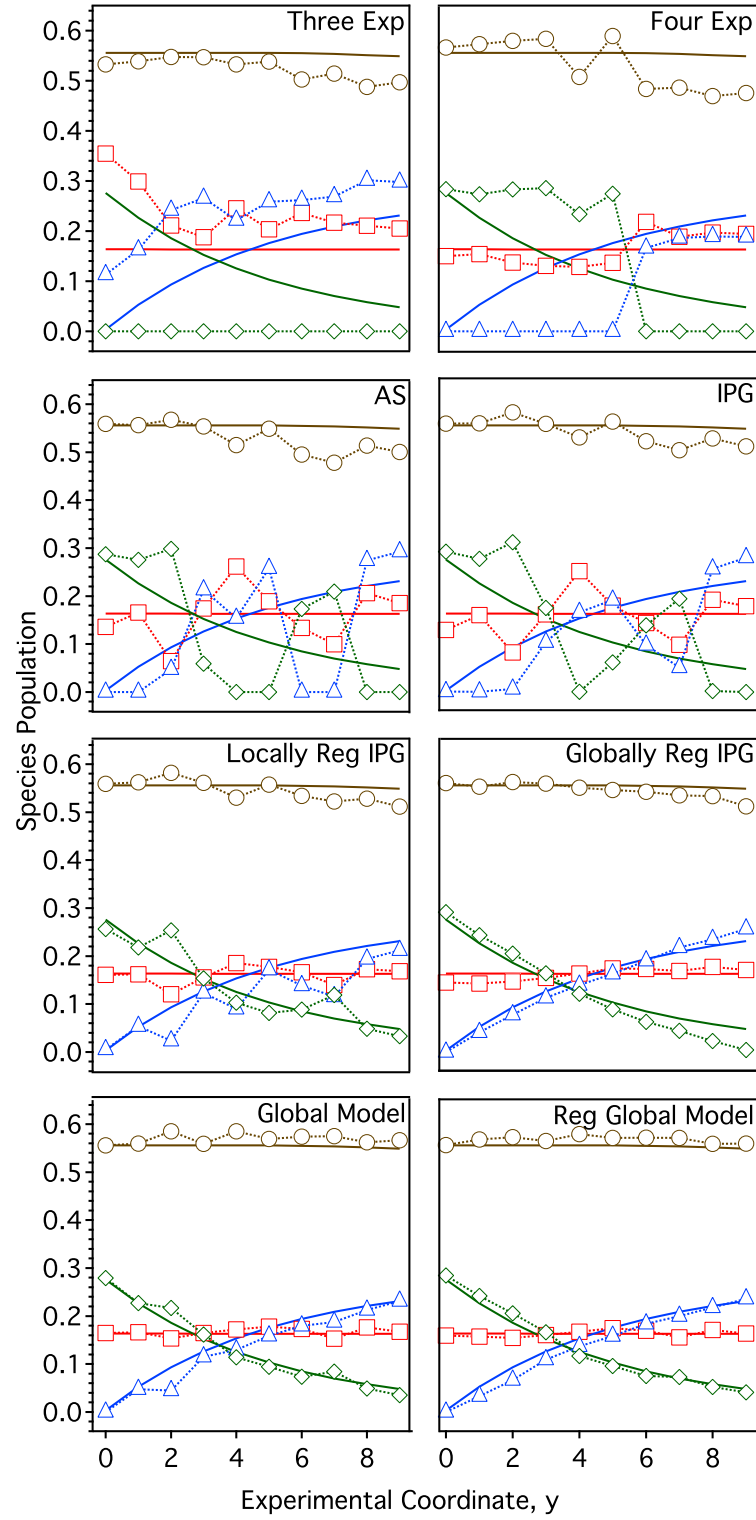

Figure 2.14: Species Populations, S_i, at $\mathcal{I} = 10^4$). Species **1** through **4** are represented by brown ◯, green ◇, blue △, and red ▢ respectively. The solid lines of the same respective color, represent the exemplar species populations, $\tilde{S}_i$.

Population Evolution

The POP parameter in Fig. 2.13 measures the overall ability of the fit to extract the evolution of the populations, while the individual populations of the different species appear in Fig. 2.14. The globally regularized IPG began improving at a lower signal level than the other IPG methods, however at higher signal levels the other methods eventually caught up. The MEM fits were comparable to the locally regularized fits for low S:N but after $\mathcal{I} = 2 \times 10^3$ the MEM was worse and did not catch up until the higher accuracy of our MEM implementation became important in the high S:N limit ($\mathcal{I} = 10^8$)). The global regularizer could not do a perfect job tracking the population evolution because it inherently measures deviation from a linear dependence of the evolution in y. As a result the evolution was "flatter" than it should have been as shown in Fig. 2.14 right column, third row. Once it is known that there are a certain number of species and that they are evolving, the regularizer could be modified to allow more curvature in the evolution by measuring departure from piecewise quadratic behavior with a third derivative regularizer. However at the level of reconstruction afforded by the second-order global regularizer, one would be better served forming a phenomenological model describing the evolution and fitting to that global model to extract physical parameters from the data.[7] Prior knowledge in this case arises from the formation of a physical hypothesis and allows the global models to get a better solution. The traditional global model and regularized global model illustrate this point as they both did an excellent job reconstructing the populations and their evolution.

2.5.2 Prior Knowledge and Probabilistic Constraints

For all reasonable S:N levels, an investigator considering the value of χ_r^2 and the F-test would be led to choose the three exponential model. If one also considered the

details of the experiment and used that prior knowledge in the fitting procedure one would obtain better results in terms of identification of the species present, their properties in terms of the transformed coordinate, k, as well as evolution of their populations across the non-transformed coordinate, y. Stabilization by global fitting works because the model space is being limited. To start with a deterministic global model would be to start with an assumed answer and eliminate all other regions of model space.

We saw how the addition of a regularization condition in the transformed dimension, k, perturbs not only the narrow distributions of Species **2**, **3**, and **4** but also increases the width of the broad distribution of Species **1**. The broadening from the regularizer masked the evolution of the Species **1** width. We see that the regularized IPG gave fits that were no better and were in some ways worse than than those given by unregularized IPG. This is because the transformed-coordinate regularizer is adding *incorrect information* to the fitting procedure.

In the case of the three exponential, four exponential, and AS fitting there was also incorrect information being added to the fitting procedure. In the case of the three and four exponential fits, the incorrect information was that the distributions are discrete. This limits the solution space available for the fits to the point where no correct solution can be found because the correct solution is not included in the space of possible solutions. The space of possible solutions for the AS method fits includes the correct solution, however the search space includes solutions that are not in the space of possible solutions. The algorithmic mechanism used to return the search from the forbidden space to the allowed space is what biases the fit away from the correct solution. In locally regularized IPG the local solutions are biased away from solutions that include discrete or sharp features and thus, though the available solution space includes the correct solution, the regularizer puts an *a-priori* bias against it because it includes narrow features. When viewed in this light, it is understandable why regularization in

the transformed dimension is not a physically reasonable thing to do.

The global regularization worked well because there was an evolution of the system across y. If there were no systematic trend with the independent variable then it would not be sensible to regularize the data with the condition of piecewise linearity implied by Eq. 2.8. This method of global fitting may also be applied to systems without a second independent variable by using replicate measurements and a regularizer that is appropriate for a non-evolving system.

$$\mathcal{G}(y) = \int \left[\frac{\partial f(k, y)}{\partial y} \right]^2 dy. \tag{2.26}$$

This regularizer measures departure of $f(k, x)$ from a constant in the y direction.

In systems that are strongly evolving the third derivative regularizer can be useful as it measures piecewise deviation from a parabola:

$$\mathcal{G}(y) = \int \left[\frac{\partial^3 f(k, y)}{\partial y^3} \right]^2 dy. \tag{2.27}$$

Other regularizers could be used as well, so long as they can be placed into matrix form as in Eq. 8.2.

Though the different regularizers imply different prior knowledge of the experimental design, they do not forbid non-conforming solutions. They only favor conforming solutions to the degree dictated by the strength of the regularizer parameter, γ. Since γ is restricted to be weaker than any level that causes an increase in χ_r^2 that is significant as determined by the F-test, one can be assured that the fit obtained is statistically indistinguishable from that of an unregularized fit. The prior knowledge of the experiment is only biasing within the set of solutions that are statistically the same.

2.5.3 Global fitting strategy

The goal of global analysis is to identify the species present and characterize their evolution with the non-transformed coordinate y. An additional benefit of
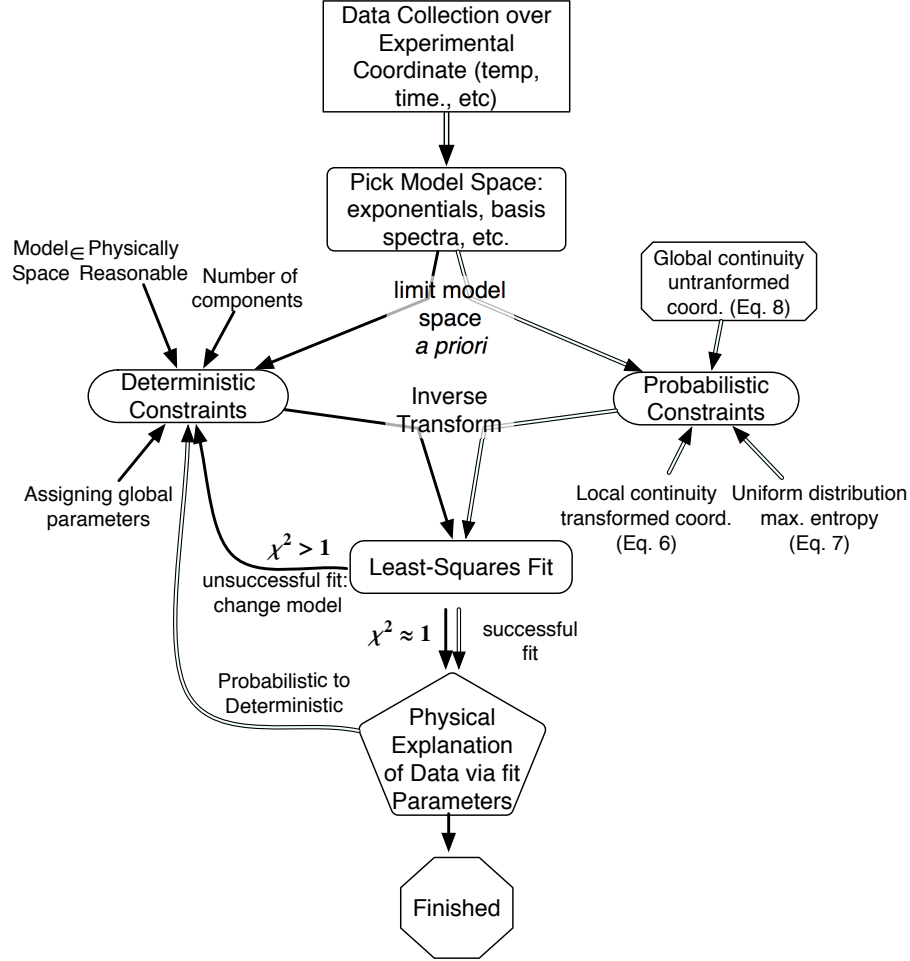

Figure 2.15: Model selection vs model discovery Current paradigm of global analysis follows the thin solid lines. In this case, a model is selected first with deterministic constraints *a priori*,the quality-of-fit is evaluated and a new model is chosen if necessary. Following the double lines, we propose using globally regularized method to discover the model of the evolution of the system based on the data and prior knowledge. Once a model is discovered, deterministic constraints can be applied in order to reach conclusions about the underlying physical system.

global analysis is that a given local solution, when fit globally, is actually using information from all the decay curves and therefore behaves as it if has better S:N. The global analysis essentially allows the amount of signal (information) for the entire data set to be used for the global parameters. For local parameters the benefit is indirect. However, having more stable values for the global parameters results in more stability in the local parameters as well. Global regularization allows this to occur without requiring a specific model and without enforcing

a value on a global parameter. Even when a traditional global model is used a regularizer can allow partial globalization of the non-global parameters. The non-global parameters are essentially free of the model. In the present example the global model would have needed to be expanded to include a specific functional form for the evolution of the population parameters.

Fig. 2.15 illustrates a fitting strategy that step-wise reduces the available model space according to the data and prior knowledge. This allows fitting of the global data set without sacrificing the range of the model space while still allowing quantitative conclusions to be drawn. Initially one should use prior knowledge to determine the range of valid k for the inversion. Alternatively this could be done with a traditional multi-exponential LM fit or a large-grid AS fit. Once the model space has been identified, one should use prior knowledge of the experimental design to determine if there should be some expectation of continuity or other regularization condition in either or both of the coordinates k and y. Once a probabilistically constrained model space is available, one can perform a global fit that includes all the model space using the globally regularized IPG method. From the globally regularized IPG fits one should identify the species present and form a deterministically constrained global model for the transformed (species) coordinate. A traditional global model can then fit the data either with or without a probabilistic constraint on the non-transformed (evolution) coordinate. At this point a global model for both coordinates should be apparent and further reduction based on a fully deterministic physical model with a small number of parameters should be feasible.

2.6   Conclusions

Current physical measurements include complex systems that do not give simple homogeneous signals. Large heterogeneous data sets measured over many conditions have become the norm. Extracting physical information from such data sets requires handling large model spaces in the fitting procedure. Fitting with large numbers of basis functions such as is done in this work has only recently become feasible. The complexity of the global regularization method would have been prohibitive given the computational facilities commonly available 10 years ago. Many of the assumptions for approaches to and algorithms for data fitting and reduction were shaped by technological limitations of 20 or more years ago. Modern computers allow direct fitting of large data sets and should be exploited to allow better insight into the processes behind the data.

Chapter 3

β-Lactoglobulin Assembles into Amyloid through Sequential Aggregated Intermediates

3.1 Summary

We have investigated the aggregation and amyloid fibril formation of bovine β-lactoglobulin variant A with a focus on the early stages of aggregation. We used time-resolved non-covalent labeling with thioflavin T and 1-anilino-8-naphthalenesulfonate to follow the conformational changes occurring in β-lactoglobulin during aggregation. 1-anilino-8-naphthalenesulfonate monitored the involvement of the hydrophobic core/calyx of β-lactoglobulin in the aggregation process. Thioflavin T luminescence monitored formation of amyloid. The luminescence lifetime distributions of both probes showed changes that could be attributed to conformational changes occurring during and following aggregation. To correlate the luminescence measurements with the degree of aggregation and the morphology of the aggregates, we also measured dynamic light scattering and atomic force microscopic images. We evaluate the relative stability of the intermediates with an assay sensitive to aggregation reversibility. Our results suggest that initial aggregation during the first 5 days occurred with partial disruption of the characteristic calyx in β-lactoglobulin. As the globular aggregates grew from days 5-16, the calyx was completely disrupted and the globular aggregates became more stable. After this second phase of aggregation, conversion to a fibrillar form occurred marking the growth phase and still more changes in the luminescence signals were observed. Based on these observations we propose a three-step process by

which monomer is converted first to weakly-associated aggregates that rearrange into stable aggregates that eventually convert to protofibrils that elongate in the growth phase.

3.2 Introduction

3.2.1 Amyloid Formation

Aggregation of soluble polypeptides or proteins into insoluble amyloid fibrils containing the cross-β structural motif has been observed in the progression of over 20 diseases.[1] The human health impact of these diseases has motivated intensive study and numerous reviews of the structure and growth of amyloid fibrils.[1, 2, 3, 4, 5, 6, 7, 8, 9]

Amyloid formation often shows a sigmoidal kinetic growth pattern. Early times are characterized by a lag phase where little or no fibrillar growth is observed. The growth phase follows where amyloid rapidly assembles. The reaction then slows with amyloid accumulation reaching a plateau.[10, 1, 11] After this point amyloid often begins to gel or precipitate *in vitro*. The duration of the lag phase and the growth phase both change dramatically depending on the incubation conditions.[12, 13, 14]

The kinetic lag phase for many amyloidogenic precursors is characterized by conversion of soluble monomers to small oligomers.[15, 10, 14] One of the driving forces for initial aggregation of soluble globular proteins may be the partitioning of hydrophobic side chains into a central core, much like protein folding.[16] The structural content and contribution to amyloid assembly of the small oligomers is usually only inferred.[17, 18] During the lag phase there is little appreciable amyloid formation as determined by histological assays. The lag time can be reduced or eliminated by addition of mature amyloid as observed both *in vivo*, by mortality of the organism and/or autopsy with histological staining [19], and

in vitro as monitored by light scattering or staining.[20, 12, 21] This leads most investigators to associate the lag phase with the formation of a critical seed or nucleus.[20, 15, 17, 22] The kinetic evidence of a critical seed has not been corroborated by either structural evidence identifying it or direct mechanistic information of how it forms and grows.

The kinetic growth phase shows rapid assembly of amyloid. Amyloid filaments and fibrils have been identified in atomic force microscope (AFM) and electron microscope images during and after the growth phase.[23, 24, 25, 26, 21] During the growth phase it is most often observed that the kinetic rate is first order with respect to precursor concentration.[27, 13, 28] Based on images and simple kinetics, mechanisms have been proposed,[11] but are not well-established. A template or seed has been proposed to be required for the growth phase to occur.[29] Growth then occurs as the template either actively induces structural changes in other species or passively aggregates with other species also having the correct template.[30]

Recent evidence has shifted some of the focus from amyloid fibrils to prefibrillar amyloidogenic aggregates as the cause of Alzheimer's disease symptoms[2, 18] leading many to propose development of vaccines targeting small amyloidogenic aggregates.[4, 31, 6] It remains a challenge to distinguish between small oligomers that are harmless and those that are either toxic in their own right or that lead to formation of amyloid fibrils.[18]

Many amyloidogenic peptides and proteins exhibit conformational polymorphism; they can exist in multiple stable conformations.[32] Conformational changes are typically observed during amyloid assembly. In their native state, the precursor proteins may not, in general, contain the secondary structural elements present in the final amyloid assembly.[33] The amide I infrared absorption or Raman band has been observed to lose intensity associated with the native state and gain intensity associated with cross-β.[34, 35, 25, 32] Circular dichroism of
Figure 3.1: *The possible binding sites of ANS to β-LGA.* Hydrophobic amino acid residues are colored in slate, hydrophilic residues in brick. ANS was docked to β-LGA using PyMOL, and minimized using molecular mechanics software IMPACT.[86] The left panel is a 16 $\mathring{A}$ slab of the van der Waals surface without secondary structure to illustrate the binding of ANS in the hydrophobic calyx site (A). The right panel is rotated 90° about vertical axis of left panel to show the postulated intercalation site in the hydrophobic region between the main α-helix and β-barrel surface patch (B). Roughly two-thirds of the calyx volume is represented by its "mouth" and may be considered to be a third ANS binding site (C).

the peptide backbone absorption band is also sensitive to secondary structure and has given similar results.[36, 37] Fluorescence spectroscopy has been used to detect conformational changes either by non-covalent labeling with dyes like 1-anilino-8-naphthalenesulfonate (ANS) that are specific for exposed hydrophobic patches[38, 39, 40, 41] or through covalent attachment of fluorescent dyes.[42, 43]

3.2.2 Bovine β-lactoglobulin variant A

We investigate the mechanism of amyloid formation from β-lactoglobulin variant A (β-LGA) with a particular focus on the aggregation and structural changes occurring during the lag phase. Bovine β-LGA (MW 18.3kD/monomer) is a member of the lipocalin superfamily of proteins consisting of a flattened β-barrel

or calyx comprised of eight β-strands (Fig. 3.1). β-LGA also has a partial ninth β-strand and a three-turn α-helix.[44] β-LGA is dimeric under native conditions. β-LGA has two disulfide bridges and a single free cysteine that has been observed to undergo disulfide exchange only when denatured.[45]

$\beta-$LGA has been shown to form amyloid fibrils.[37, 13, 25, 46] The folding behavior of β-LGA has been extensively studied using bulk experiments.[45] β-LGA has structural elements that are conformationally labile.[47, 48, 49, 50, 51, 52] β-LGA can exist in an equilibrium between folded, partially structured, and unfolded states.[53, 47, 37, 48, 49, 13, 50, 51, 54, 52, 55, 56, 57] β-LGA has been reported to form non-native α-helices prior to complete folding.[53, 48, 49, 13, 50, 51, 54, 52, 55] NMR has shown that these α-helices must melt and form a β-strand to complete the native-state structure.[52] The stabilization of βLGA by trehalose was studied using acrylodan covalently attached to cysteine 121, which showed conformationally sensitive fluorescence. Conformational fluctuations in β-LGA transmitted to the local environment of the attached acrylodan resulting in a spectral shift as well as lifetime, intensity, and anisotropy changes.[58]
Figure 3.2: *AFM images of β-LGA aggregation under amyloidogenic conditions.* Days 10, 22, 29, and 65 are shown as labeled. Images are colored by height and approximately correspond to species described in the text. AFM heights are uncorrected for tip penetration of the soft samples. Prior to day 10, there was little indication of stable aggregates adhering to amino-silanized mica surface. The first sign of small stable oligomers (shown in green) appear at day 10. The total number and aspect ratio of the aggregates increases through day 22. After four weeks, small protofibillar species are apparent and range from 50 to several hundred nanometers in length. Fibrillar species ranging in height and length dominate at two months of incubation. Large amorphous aggregates appear as early as day 10, but appear to be off the amyloid formation pathway.

3.2.3   Biophysical Approaches to Aggregation

In this paper we use ANS fluorescence lifetime distributions to follow the aggregation of β-LGA through its lag phase intermediates until it forms amyloid fibrils. It has been previously reported that the fluorescence lifetime of ANS is influenced

by the polarity of its binding environment, specific interactions with amino acid side chains, and the relative orientation and mobility of the anilino group.[59] ANS binds to hydrophobic regions of proteins[60], and has been extensively used to probe the presence of the molten globule state and assembly of partially structured proteins.[40, 61, 13] ANS has been observed to have different fluorescence intensity properties when bound to different types of protein aggregates.[62] β-LGA binds ANS in several ways,[58] including through the calyx that results in a sequestered ANS with a very long lifetime (see Fig. 3.1). ANS probes both the presence and integrity of this calyx as well as the overall exposure of hydrophobic groups in β-LGA. The calyx is of particular interest because it is the majority of the hydrophobic core of β-LGA. Disruption of this core is required for an aggregate to fulfill the geometric constraints of the cross-β structure of an amyloid fibril. We use our globally regularized interior point gradient (GIPG) fitting procedure that fits all the data simultaneously to resolve the contributions of different ANS binding sites to the fluorescence lifetime decay.[63]

We expect aggregation to be driven, in part, by hydrophobic forces. Therefore the parts of the protein that can bind ANS should be structurally changed by aggregation. The ability to detect the presence of an intact calyx by virtue of ANS binding allows determination of the involvement of, and structural changes in, the protein hydrophobic core during amyloidogenic incubation. If the aggregation process is hydrophobically driven then we expect the aggregate to sequester hydrophobic residues changing the structure of the calyx. Alternatively if hydrophobicity the key driving force for conversion to the cross-β structure, then the large changes in the calyx should occur at that point in the incubation. In either case the sensitivity of ANS to its binding environment should be reflected in its fluorescence lifetime distribution.

We confirm early stages of aggregation using dynamic light scattering (DLS). DLS has been used extensively to characterize protein aggregation and the growth

of amyloid.[64, 65] We explicitly evaluate the evolution of the particle size distribution using the GIPG fitting procedure.[63]

We assay for the presence of amyloid using Thioflavin T (ThT) luminescence. When bound to amyloid, ThT exhibits a new absorption band at 450 nm that has been attributed to ThT binding to the cross-β structure.[66, 67, 68, 69, 13, 70] The spectroscopic properties of ThT in amyloid are consistent with behavior that has been attributed to ThT dimer formation.[71, 72, 73] The lifetime of such a dimer will depend on its environment and geometry and some contribution of the luminescence may arise from non-amyloid binding modes.[74] We exploit this to detect the presence of various amyloid-like structures using a ThT luminescence lifetime assay. The different lifetime distribution contributions and their evolution is determined using the GIPG procedure.

We determine the morphology of the aggregates using AFM imaging. Imaging techniques such as AFM have provided an invaluable way to determine gross morphologies of amyloid protofibrils (single-stranded) and fibrils (multi-stranded).[23, 25, 26, 75]

3.3   Results

3.3.1   AFM shows sequential growth of aggregates

Fig. 3.2 shows AFM images taken on several different days of the incubation. The images are false-colored by height to emphasize the contrast between different classes of particles. AFM images taken from days 0 to 9 of the incubation did not show significant signs of aggregation. The protein deposited as a uniform coating on the functionalized mica surface (brown background in Fig. 3.2). Starting from day 10 of the incubation, we began to see small round aggregates (green dots in Fig. 3.2) that grew in size and number through day 22 (orange dots in Fig. 3.2). After day 22 the number and length of oblong protofibrils increased (purple bars

in Fig. 3.2). Eventually long fibrillar aggregates were observed (Fig. 3.2). Large amorphous aggregates were also observed (white features in Fig. 3.2) but appeared to evolve independently of the other species.

The AFM results suggest two acts to aggregate growth. The first act consists of formation of round aggregates that can be stably imaged on the functionalized mica surface. The second act features the elongation of protofibrils. Each of these processes appears to have an induction period of 8-10 days under our incubation conditions. A complete analysis of the evolution of the AFM particle size distribution is the subject of a forthcoming paper.

3.3.2 DLS resolves early lag phase aggregation

DLS correlation functions were measured every 15 minutes for 4.7 days to investigate the earliest aggregation events. Distributions of correlation decay times appear in Fig. 3.3. The width at 5 M urea was greater than it was at both lower and higher urea concentrations where the protein is a native monomer (2.5 M) and unfolded (7.5 M), respectively. This was consistent with literature reports that at 5 M at neutral pH, β-LGA intermediate and denatured states are in thermal equilibrium.[76] From day 0 to day 2 the position of the peak max moved from the monomer decay time to the the dimer decay time. By day 4 of incubation, the peak max moved to the position expected for the tetramer decay time.

Fig. 3.4 shows the evolution of the DLS decay time distribution taken every 2 days for the first 28 days of incubation. The 0-4 day evolution matches that of Fig. 3.4. The peak max of the small aggregate region did not substantially change after day 4. The peak width was broader than expected for a monodisperse tetrameric aggregate. From days 10-18 a shoulder appears in Fig. 3.4 to longer decay times suggesting growth of a minority species of larger aggregates. A weak and broad peak grows in slowly from days 12-18 at $\sim$1.5 ms and becomes appreciable from days 18-28. At these later stages the large distribution

of particle sizes and shapes prevents specifying these quantities in terms of the ensemble-averaged DLS decay time distribution.

Interpretation

The DLS data suggests three phases of aggregation. Aggregation of the monomer proceeded rapidly within the first few days of incubation. Non-reducing SDS PAGE analysis after 5 days of incubation stage showed mainly disulfide-linked dimers with some monomers. The motility of the monomers that were still present was consistent with their native disulfides still being intact. This suggests that oxidative aggregation does not exceed the dimeric state, consistent with only a single exchanging cysteine per monomer. Upon accumulation of the approximately tetrameric aggregate, a new phase begins. Further changes showing increases in particle size appeared during days 10-18, suggesting another mode of aggregation. The contribution of these particles to the DLS signal eventually was swamped by the contribution of the large particles that appeared in significant numbers from day 18 onward. Late-stage (>30 days of incubation) SDS PAGE showed similar results with the concentration of the dimers about 50% of that of the monomers. Again the motility of the monomers was greater under the non-reducing conditions than under reducing condition. The lack of disulfide cross-linked aggregates of higher order than dimers at late stages is consistent with higher-order aggregation being associated with non-covalent interactions.

3.3.3 ThT tracks structural conversions

We used a Thioflavin T assay to evaluate the point in the incubation when the aggregates converted to amyloid. Steady-state luminescence measured during incubation shows the classic sigmoid curve that is often associated with amyloid formation. As seen in Fig. 3.5, the individual lifetime contributions to the signal, however, have a very different behavior.
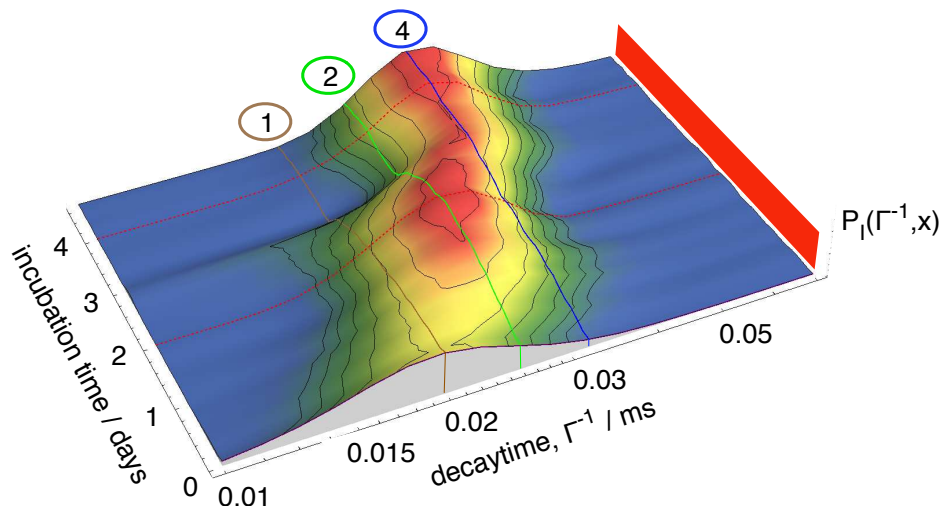

Figure 3.3: *GIPG fit of DLS correlation functions for the 4.7 day incubation of β-LGA.* A continuous acquisition DLS experiment allowed investigation of the earliest aggregation events. During the first hour of incubation, the hydrodynamic radius of β-LGA was consistent with a partially unfolded monomer at 2.5 nm (shown as a brown mesh line (1)). If the aggregation preserves the density, the decay times of approximately spherical dimeric and tetrameric species can be calculated; they are represented by the green (2) and blue (4) mesh lines, respectively. The monomer was converted to mostly dimer by day 2, then tetramer by day 4.

When measured in buffer, ThT shows four contributions to the lifetime distribution, and we speculate that the different lifetimes arise from different ThT aggregate geometries free in solution.[71] ThT in the presence of unincubated β-LGA shows an additional lifetime contribution at ∼110 ps not present in the protein-free control. β-LGA is known to bind hydrophobic molecules and therefore some luminescence changes associated with this binding to the monomer is expected. It is also possible that a single β-LGA could bind two ThT molecules creating a small amount of dimer signal, as was shown by intercalation of ThT in γ-cyclodextrin.[72, 73]

The ThT liftetime distribution was substantially different at each phase of
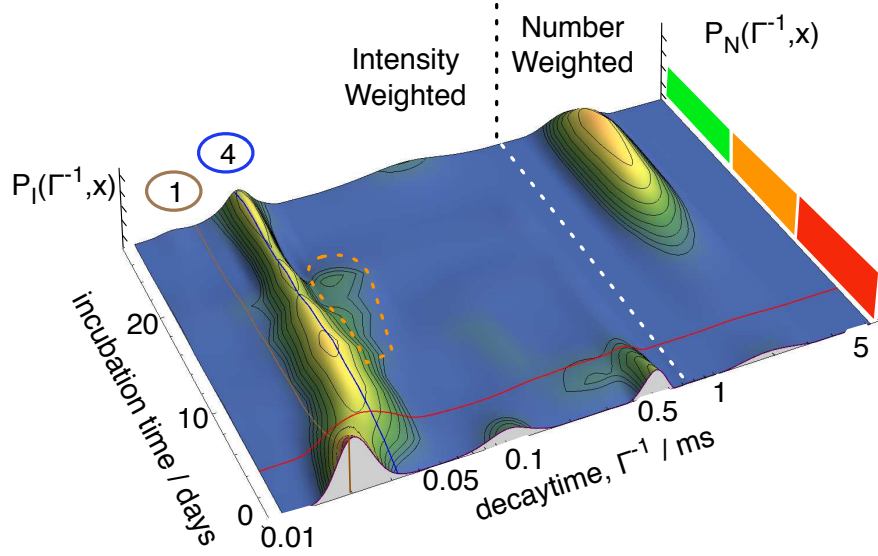

Figure 3.4: *GIPG fit of DLS correlation functions for the 28 day incubation of β-LGA.* Mesh lines (1) and (4) are the same as in Fig. 3.3. The high-resolution DLS fits coincide with the first few days of the 28 day incubation. A shoulder appeared at day 10 and separated from the tetramer species at day 18 (orange dashed contour). This feature has a decay time characteristic of a small, inflexible rod of length ranging from 15 to 30 nm with the same radius as the tetramer. The red, orange, and green color bars represent a rough estimate of the early, mid, and late phases that we have consistently observed throughout our experiments. The white mesh line demarcates the intensity and number weighted representation of the decay times allowing the entire data set to be presented together.

the incubation. During the beginning of the lag phase, days 0 to 5, we saw a decrease in the contributions that are present in the ThT-only control. The relative contributions of these components also changes. This behavior suggests that the aggregation in the early lag phase is reducing the solution-phase portion of the ThT in favor of protein-partitioned ThT. During the lag phase, days 9-18, we saw a different pattern emerge in the lifetime distribution. Several new lifetime features appear ranging from 75 ps to 2.2 ns.

After day 18 the distribution began to change rapidly as shown by growth of a feature at 2.6 ns followed by a feature at 1.3 ns. At day 32 the majority of the
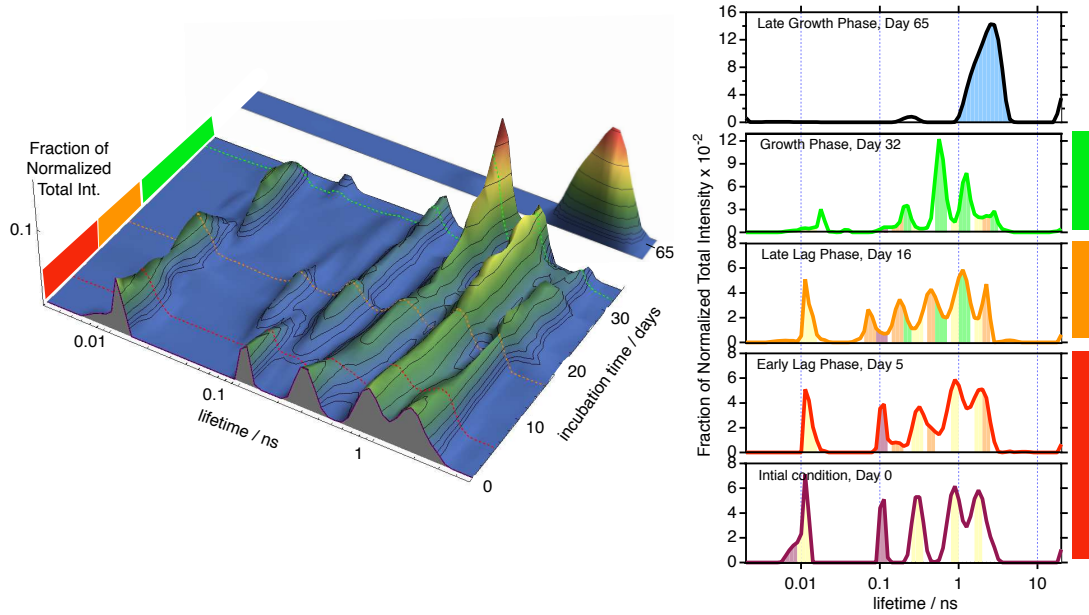

Figure 3.5: *GIPG fit of ThT luminescence decays in the presence of β-LGA over a 28 day incubation.* Left panel: The evolution of lifetime distributions show the onset of luminescent species occurs in stages. The reduced chi-squared (χ_r^2) for this global fit was 1.022. Right panel: Incubation time slices of ThT lifetime distributions with different contributions at days 0, 5, 16, 32 and 65 are as labeled and correspond to the dotted mesh lines in the right panel. To depict the growth and loss of different luminescence components along the incubation timecourse, the distributions are filled to the baseline with colors corresponding to the trace where the particular component dominates. For example the green filling matches the peaks at day 32, but the same components are less prevalent at day 16.

luminescence signal is coming from 580 ps lifetime. The short-lifetime feature at 11 ps disappeared and was replaced by a feature at 18 ps that attained a maximum at 26 days and then disappeared by 33 days. After 2 months of incubation, the distribution is dominated by a broad asymmetric peak at 2.6 ns with a smaller contribution at 250 ps.

There are clearly multiple contributions to the ThT lifetime distribution. Each phase of the incubation has a distinct lifetime distribution suggesting that ThT associates with many different aggregates in structurally different ways. We observed that significant ThT luminescence grew in during the earliest stages of incubation (Fig. 3.5). These changes in an intensity-only experiment might be

interpreted as a baseline shift. The association of monomers into a disordered aggregate may provide ThT with the opportunity to form dimers that show luminescence similar to amyloid, however the lack of a regular geometry results in a different lifetime. Particularly striking is the difference between the 580 ps contribution that seems to appear in association with protofibrils and the 2.6 ns contribution that appears in the late-stage aggregation where mature amyloid fibrils are present. The signal from ThT usually associated with histological staining is probably most closely related to the distribution from the 65 day sample. The ThT signal changes that contribute to the classic sigmoidal intensity kinetic trace are most likely due to other binding modes and luminescence lifetimes. This suggests that the pro-amyloid ThT luminescence has a structural sensitivity that is reflected in its luminescence lifetime distribution. ThT assays based only upon intensity could be misleading since there are several contributions to the luminescence that are potentially changing during incubation. The contributions from the different species cannot be resolved from intensity alone.

3.3.4   ANS reports changes in hydrophobic regions and calyx loss.

The fluorescence lifetime of ANS was measured during 28 days of amyloidogenic incubation. We used GIPG as a model-free approach to determine the evolution of the ANS fluorescence assay lifetime distribution. We observed several peaks in the distribution that change systematically with incubation time and labeled them (a) though (i) for clarity as shown in Fig. 3.6. Some of these peaks change during the first several days of the incubation. Others grow in at the late stages of the incubation. The evolution of individual peaks can be associated with the changes in the availability of specific binding environments on β-LGA in its various aggregation states. To directly evaluate the evolution of the contributions from
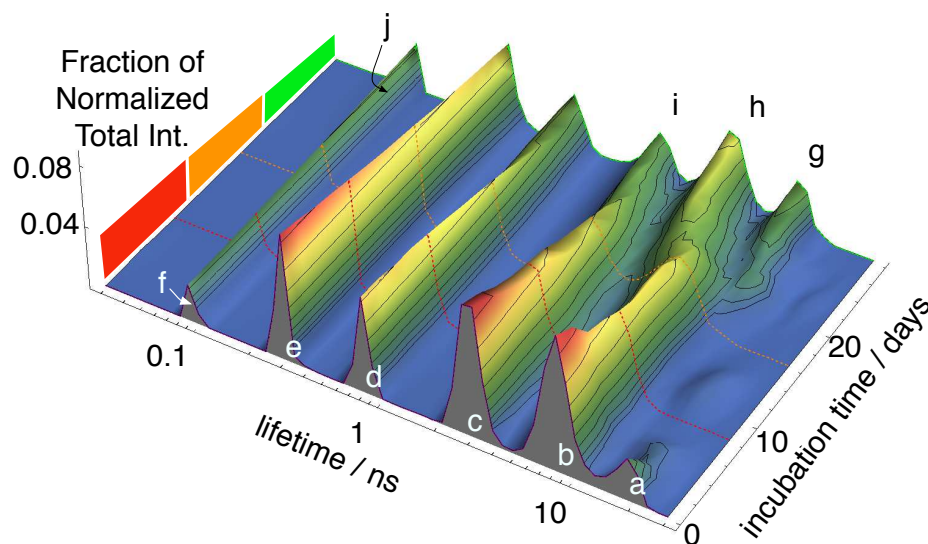

Figure 3.6: *GIPG fit of ANS fluorescence decays in the presence of β-LGA over a 28 day incubation.* The χ_r^2 for this global fit was 1.019. The distribution of fluorescence lifetimes showed the variety of binding environments for ANS and their systematic population changes changes with incubation time. The reduction of some peaks (i.e. **a**, **b** and **c**) and the increase of others (i.e. **g**, **h**, **i**) reflected the conformational changes experienced by β-LGA as it assembles into fibrils. All peaks are assigned to different ANS environments in the text. This model-free fit was used as the basis for further data reduction as described in the text and shown in Fig. 3.7.

each sub-population of ANS, we constructed a reduced basis set representing each peak from the original GIPG fit as a separate function. The Laplace transform of each of these peaks was convoluted by the instrument-response function in this simplified basis set. The population of each contribution as a function of incubation time appears in Fig. 3.7. These sub-populations of ANS binding were then assembled into lifetime distribution fingerprints for the different species along the amyloid formation pathway.

ANS is quenched by full exposure to 5 M urea and gave a lifetime of ∼300 ps (**e**) in our control experiments. This contribution appeared to decrease as the
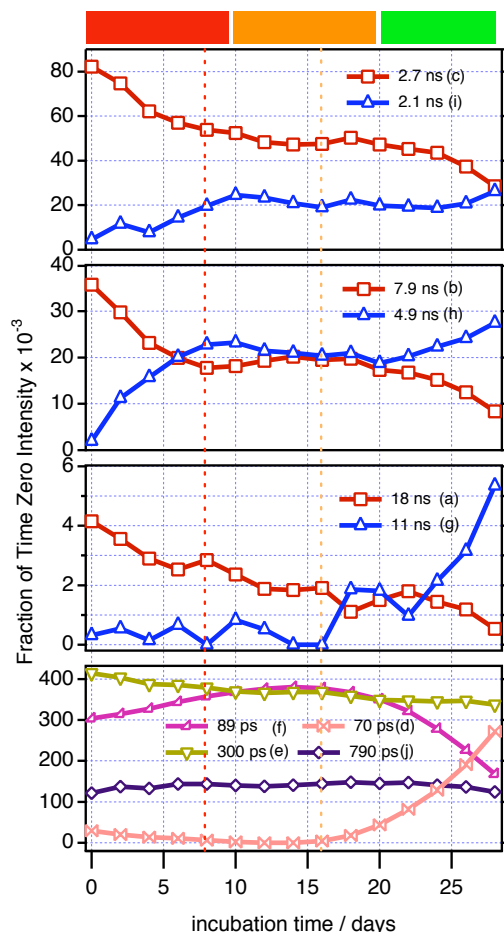

Figure 3.7: *Sub-populations of ANS binding to β-LG*A *over a 28 day incubation using GIPG with reduced basis set.* The χ_r^2 for this global fit was 1.020. In the top three panels, the red squares represent the decreasing lifetimes and the blue triangles represent increasing lifetimes corresponding to the sub-populations in Fig. 3.6. The species lifetime evolutions are associated with a change in the ANS environment in the calyx or surface sites. The bottom panel shows the trends of the short lifetime components. The lettering **(a)** though **(i)** matches the peaks in Fig. 3.6. The red and orange dotted vertical lines mark the lifetime components at days 8 and 16 which were combined with those at days 0 and 28 to generate the characteristic "fingerprints" of the ANS-bound protein species and shown in Fig. 3.8.

incubation progressed. This suggested an increase in the partitioning of ANS with the protein as compared to the solution and was consistent with an overall increase in the availability of hydrophobic binding sites as the incubation proceeds.

The model-free GIPG fit in Fig. 3.6 shows an 89 ps feature (**f**), which was

also present in the ANS lifetime distribution from 1 to 6 M urea in our control experiments, but only when β-LGA was also present. This feature appeared to increase in population from days 0 to 14 then decrease from days 16 to 28. The 89 ps contribution overlapped with a broad lifetime contribution at 70 ps (**j**) that grew in starting at day 18. The increase in this contribution appeared to compensate for the loss of the 89 ps contribution. These lifetimes were significantly shorter than that of the free ANS, suggesting a quenching interaction with an amino acid side chain.

The monomeric signal included contributions from peaks at 18.2 ns (**a**), 7.9 ns (**b**), and 2.7 ns (**c**). The peak at 18.2 ns was close to the unquenched lifetime of $\sim$19 ns predicted by an evaluation of the oscillator strength using the Strickler-Berg equation.[77] This suggested that ANS was sequestered from any quenchers and was protected from water, consistent with an intact calyx. This feature decreased throughout the incubation. ANS can induce structure in proteins and the presence of folded β-LGA under these conditions may be a result of this effect. No other lifetime feature in the distribution appears to compensate for the loss of the 18.2 ns feature.

The peak at 7.9 ns (**b**) also suggested protection from water, though to a lesser degree. This was consistent with a partially denatured calyx. The 7.9 ns feature decreased dramatically in the first 8 days, leveling off until day 18, whereupon it continued to decrease. The changes in the 7.9 ns contribution appeared to be mostly compensated by changes in a feature at 4.9 ns (**h**). The highly anti-correlated behavior of the 7.9 ns and 4.9 ns components suggested that the 4.9 ns feature was from ANS bound to β-LGA that had its 7.9 ns calyx site disrupted by aggregation.

The peak at 2.7 ns (**c**) has been previously attributed to β-LGA surface binding.[76] Based on our ANS docking studies we found that the mouth of the calyx is a more likely assignment for this feature. The 2.7 ns feature decreased

rapidly at first, its evolution slowing after 8 days, and accelerating again during the late stages of incubation. The 2.7 ns feature population changes were partly compensated by changes in the 2.1 ns feature (**i**). Again, this close relationship leads us to conclude that the mouth of the calyx is being disrupted during the process that exchanges the population of the 2.7 ns and 2.1 ns features.

Overall, the changes in the ANS lifetime distributions occurring after day 20 were more dramatic. One of these was an 11 ns feature (**g**) that appeared to grow in at the late stages of incubation. The long lifetime suggests that ANS was mostly isolated from water. We attribute it to sequestration of ANS in the cross-β structure of amyloid protofibrils.

Not all of the lifetime features changed over the incubation timecourse. The feature at 790 ps (**d**) was present throughout the incubation with only small changes in intensity. Therefore the 790 ps site should be a structure that was not disrupted in the aggregation process. This lifetime was consistent with surface binding, which should be present at all points of the incubation. The 790 ps lifetime appeared to shift slightly at different points in the fits in Fig. 3.6. These shifts were too small to reliably resolve multiple lifetime contributions to this feature.

Any particular ANS lifetime peak can, in principle, contribute to several different aggregates. The binding location as reflected in the lifetime is sensitive to the local environment, but not the specific aggregation state. Nevertheless, the relative contribution of each binding site to a particular aggregate should be in some fixed proportion that depends on the structure of the β-LGA monomers in it. During amyloidogenic incubation we see three main phases in the kinetic evolution of the ANS lifetime distribution that are corroborated by other experiments. We seek to separate contributions of at least four species with qualitatively different aggregation states.

We assumed that the contributions of different species could be expressed as
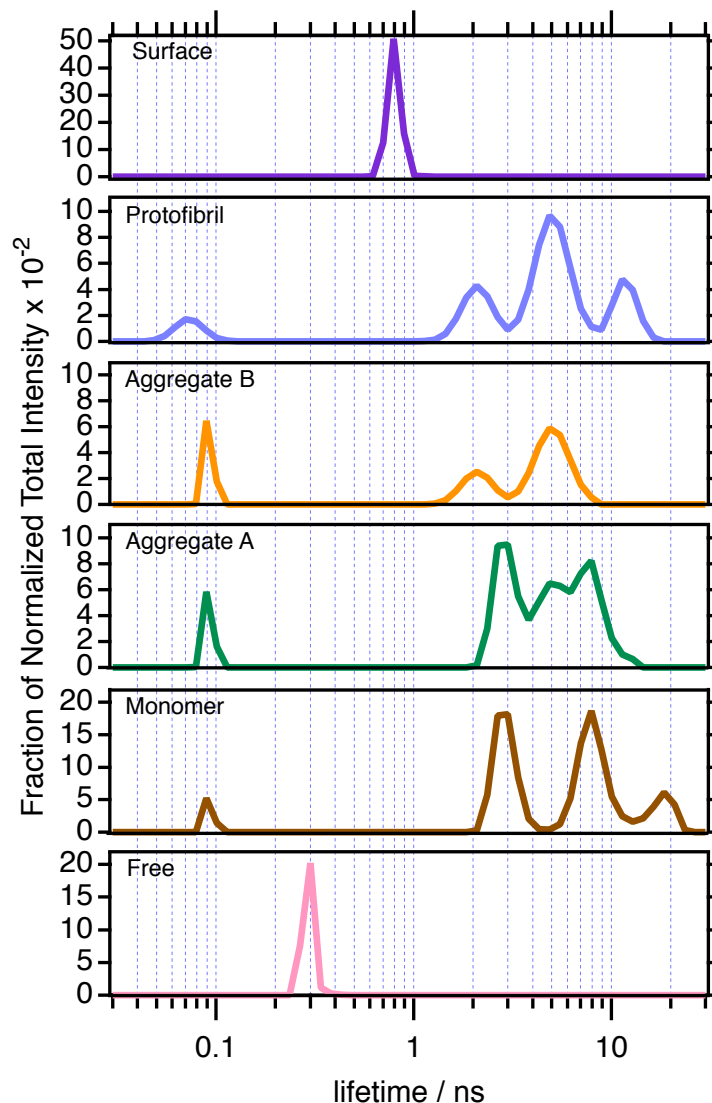

Figure 3.8: *The characteristic "fingerprints" lifetime distributions of ANS-bound* β-*LG*A. The evolution of the ANS lifetime distributions were decomposed into "fingerprint" for each species. The fingerprints are labeled in the figure and used to fit the TCSPC decays with GIPG.

linear combinations of a multi-peaked "fingerprint" describing both the relative binding likelihood and nature of the various binding modes of ANS in each species. The first fingerprint describes lifetime distribution of the various monomeric and monomer-like components. It was assigned from the day 0 βLGA urea titration control experiments. The monomer fingerprint was subtracted from the day 8 reduced basis GIPG lifetime distribution at a level that maintained non-negativity

of the distribution to obtain a difference fingerprint. We assumed this difference fingerprint was due to an early oligomeric species we designated "aggregate A" or AggA. The first two fingerprints were removed from the day 16 distribution to obtain a fingerprint we designated as "aggregate B" or AggB. The first three fingerprints were removed from the final distribution to obtain the fingerprint for "protofibrils." Fingerprints for the unbound ANS at 300 ps (**e**) and the surface ANS at 750 ps (**d**) were included separately in the fits. These fingerprints appear in Fig. 3.8. The rationale for the designations of the different fingerprints is in the discussion.

Specific differences in the contributions of the different ANS lifetime peaks can be noted for the different fingerprints. The monomer fingerprint had a different ratio of 7.9 ns (**b**) and 2.9 ns (**c**) than AggA, which also lacks the 18 ns contribution (**a**). The contribution from the 89 ps peak (**f**) increased in the AggA fingerprint which also had a new contribution at 4.9 ns (**h**). The AggB fingerprint is missing the 7.9 ns and 4.9 ns components and gained a new contribution at 2.1 ns (**i**). The protofibril fingerprint gains a peak at 11 ns (**g**) and trades the 89 ps contribution for the 70 ps feature (**j**). If a particular aggregation step does not result in a structural change, then it will not be reflected in the fingerprint, nor in the fingerprint population evolution.

Each fingerprint generated a single instrument response convoluted basis function for use in the GIPG fit. The resulting evolution of the population of the fingerprints appears in Fig. 3.9. The population of the monomer fingerprint appeared to decrease rapidly during the first 4 days of incubation. This contribution plateaued around day 8 and began to decrease again after day 24. The AggA fingerprint grew in as the monomer disappeared and reached a maximum value at day 10. It then slowly decreased until day 18, after which it decreased more rapidly. The AggB fingerprint grew in slowly beginning at day 6 pausing from day 12-16 after which it increased more rapidly reaching a peak at day 24. The
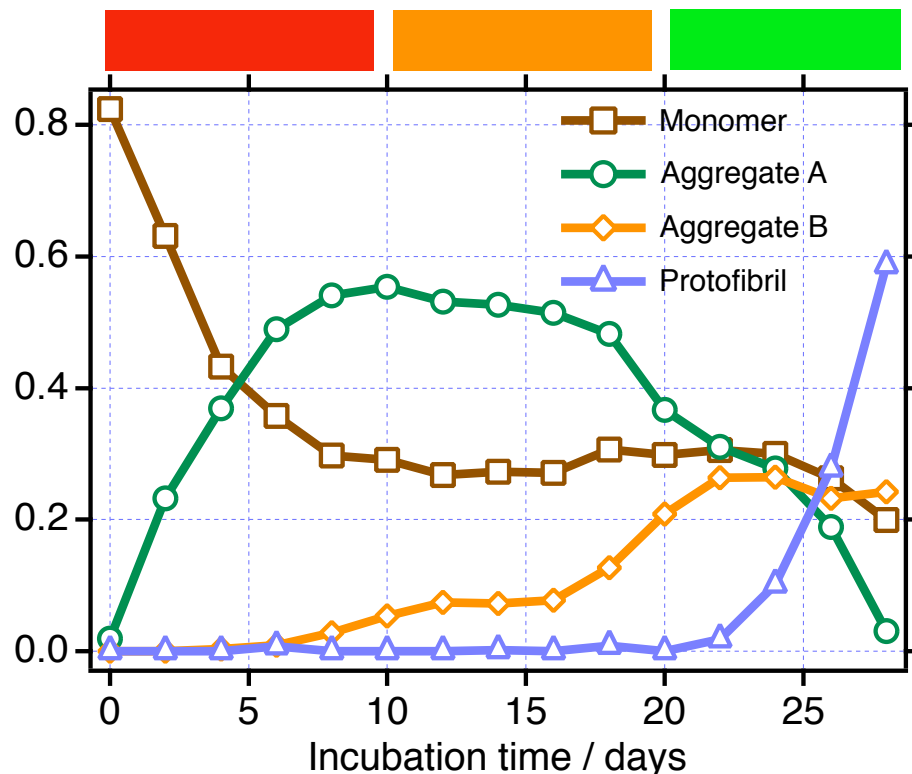

Figure 3.9: *The evolution of each fingerprint's contribution to the ANS-βLGA fluorescence decays.* The χ_r^2 for the global fit was 1.026. The evolution of monomer, AggA, AggB, and protofibril showed multiple stages of aggregation. The monomeric species decreased dramatically in the first several days and is consistent with the DLS fits 3.3. The increase in AggB from day 10 to 22 matched the accumulation of stable round aggregates in the AFM results. The increase in the protofibril species after day 24 coincided with significant changes in the ThT lifetime distributions and rod-like particles imaged by AFM.

protofibril fingerprint was flat for the first 20 days of incubation after which rapid growth occurred.

The evolution of the individual peak fits and fingerprints suggested three phases to the aggregation process. First the monomer converted to AggA; then AggA converted to AggB; protofibrils began to appear after AggB was formed in large quantities.
Figure 3.10: *GIPG fit for the ANS reversibility assay* The stability of the monomer and aggregate species are evaluated by reintroducing the incubated sample to a low urea condition. Yellow mesh lines demarcate 3.6, 4.3, 13, and 16 ns to emphasized the loss gain of species more clearly. The most dramatic feature is the nearly 50% loss of the 16 ns species, presumably the calyx-bound ANS, by day 8. The loss contemporaneously matches the change over of the 4.3 to the 3.6 ns species. The χ_r^2 for the global fit was 1.002.

ANS aggregation reversibility assay

One of the classic features of amyloid is its stability with respect to dissociation. To evaluate the amount of stabilization in different aggregates we performed the ANS assay under conditions of 0.5 M urea following incubation at 5 M urea. Under these conditions unfolded monomers are expected to spontaneously refold. If the stabilization energy of the aggregate is greater than that of the refolding reaction, then the aggregation will not be reversible upon dilution of the denaturant.

The GIPG fit to the ANS aggregation reversibility assay data appears in Fig. 3.10. The nearly constant-amplitude peak at 240 ps is consistent with ANS free in 0.5 M urea. This peak increases in amplitude during the first five days of

incubation and then decreases slightly until day 9 and then increases again with the increase accelerating after day 14.

At day 0, the peak associated with surface binding at 830 ps did not appear at its 0.5 M control experiment position suggesting that the association at this site was somewhat irreversible. From days 2 to 8 the peak was shifted to its reversible position at 1.1 ns and from days 10-18 it shifted to 790 ps. This result may indicate that there was a kinetic competition between refolding of the surface site, perhaps at the α-helix, and binding of ANS. If this is the case, it would suggest that during days 2-8 the binding site was protected from ANS until after refolding had occurred. The overall amplitude of this peak did not change much, consistent with the results of the standard ANS assay.

The peak at 16 ns was consistent with binding to the calyx and decreased rapidly from days 0 to 4 and continued to decrease more slowly from days 6 to 12. This peak was replaced by a feature at 14 ns that appeared around day 1, increased until day 14 and decreased thereafter. Around day 18 the peak shifted to 13 ns. The rapid decrease in the availability of the calyx suggests that the aggregates in the early stages prevented the binding of ANS to the calyx. The shifts in lifetime suggest that though some structure resembling a calyx can reform as late as day 18, the population of these proteins is substantially reduced and that they cannot reform the full calyx that is possible before aggregation has occurred.

We attributed the peak at 4.3 ns to the outer calyx binding site. This lifetime was shorter than the 5.4 ns we determined from the 0.5 M control measurement. This suggests a degree of irreversibility even at day 0 in this binding site. This feature decreased from days 0 to 4, leveled out from days 5 to 8, and then decayed away from days 8 to 12. This feature was replaced by a peak at 3.6 ns that increased until day 12 after which it remained steady from 14 to 18 days. Overall the qualitative behavior of this feature was similar to the feature at 16 ns.

There were essentially three manifestations of irreversibility represented in this data. The first was the ability of the protein to regain the same ANS binding sites after dilution from 5 M to 0.5 M urea as determined by the lifetime distribution. The dilution was performed in the presence of ANS. If the ANS binds to the site in question prior to refolding, then it could lock the protein into a misfolded conformation at the binding site. The result is a lifetime that more closely resembles the 5 M urea control experiment conditions than the 0.5 M urea conditions. The second type of irreversibility was the loss of a particular binding site as aggregation progresses. This suggests that the aggregate disrupts or blocks access to the site in question and that the site cannot be reformed by dilution of the denaturant. The third type of irreversibility was the replacement of one site with another. This is similar to the second type of irreversibility, except that the structural change has resulted in a new local environment for the binding of ANS.

These three types of irreversibility suggest that there are two main stages to the incubation over the range of 0 to 18 days that appear to transition at 8 to 10 days. The changes that were reflected in the irreversibility suggested that one of the key elements distinguishing the different aggregation steps was the reversibility of the interactions between monomers in the different aggregates.

3.4   Discussion

3.4.1   Conformationally lability prior to incubation

Our results suggest that βLGA was conformationally labile under the amyloidogenic incubation conditions. The Thioflavin T assay showed little change in signal over the protein-free control except for an additional peak at 110 ps. The ANS assay showed several lifetime components and a substantial contribution from intact-calyx-binding of ANS suggesting that ANS may be stabilizing the folded
Figure 3.11: *Proposed mechanism of β lactoglobulin A aggregation.* Amyloido-genic conditions put βLGA into a disordered, conformationally labile state that reversibly aggregates into dimers and tetramers that are stabilized in part by hydrophobic interactions. The calyx is intact but structurally altered. As aggregation continues, the calyx is lost and the loosely associated oligomers convert to higher order, more stable aggregates. These aggregates then convert into protofib-rils that elongate in the classic growth phase of sigmoidal kinetics. **Monomeric**: The top is the folded monomer, the middle was obtained by modeling the unfolding of the the C-terminal α-helix and β-strand I. The bottom was obtained by flattening the barrel into a sheet. **Aggregate A**: These oligomers were obtained by aligning complementary surfaces of the middle monomer structure. **Aggregate B**: This octamer was modeled by stacking the flattened monomer structure into four layers. **Protofibrils**: Four sheets of the canonical cross-β structure.

structure.[78] The multiplicity of features in the 5 M urea ANS assay suggested multiple structures for monomeric βLGA. In particular the calyx, or hydrophobic core, was more flexible and more accessible to solvent as shown by ANS fluores-cence. The reversibility ANS assay showed minor signs of irreversibility and fewer lifetime features. Under these conditions βLGA adsorbed on an amino-silanized mica surface and appeared to be denatured.

The DLS measurements showed that the protein had swelled and had a broad distribution of hydrodynamic radius. In a titration from 0 M to 7 M urea, the

width of the DLS R_H distribution was broadest at 5 M urea. That the width of the distribution is resolvable, implied the exchange time within that distribution was longer than the characteristic diffusion time of $\sim$20 μs. Amyloid formation from βLGA has been observed to be fastest at 5 M urea.[13] The day 0 DLS results showed that the conditions giving the maximum rate of amyloidogenesis were coincident with those that created the maximum variance in the hydrodynamic radius of βLGA.

Overall we can conclude that there are multiple monomeric structures that are exchanging in the sample under these conditions. The partially folded intermediate appeared to be the aggregation-prone state. The ability to exchange between multiple conformations may be a crucial feature in determining aggregation propensity. To use free energy landscape language, the folding funnel flattens, allowing access to disordered states of increased R_H and core solvation.

3.4.2 Early lag phase aggregation was more reversible

The DLS assay showed that aggregation occurs in the first few days of incubation with average particle sizes passing through a dimeric stage to a steady state with an average size consistent with tetramers. In the AFM assay, the aggregates could be imaged on a clean mica surface, but on a more strongly adsorbing amino-silainzed mica surface the aggregates were disrupted and denatured on the surface. The ANS 5 M urea assay revealed a decreased ability of ANS to bind to the calyx. The irreversibility assay showed changes predominantly in the calyx binding site. The fingerprint analysis of the ANS 5 M urea assay suggested that a new species was growing in, with a small contribution from another species. We call these species AggA and AggB, respectively. The differences in fingerprints suggested changes in the nature and relative populations of different binding sites and therefore a change in the tertiary structure of the monomers upon aggregation. However, the ThT assay only showed small changes in lifetime distribution

implying that this structural change was not to the cross-β structure associated with amyloid.

The stabilization energy of AggA was less than the electrostatic interaction with the amino-silanized mica surface. However, AggA was not disrupted by dilution into more native-like conditions suggesting that the AggA stabilization energy was between the folding energy and the surface adsorption energy. The interaction between monomers in AggA most likely involved some change or disruption of the calyx that allowed solvent access. Some parts of the structural changes that occurred upon forming AggA were still reversible at this stage. This suggested that the structure of βLGA in AggA more closely resembled the free monomer than does AggB. AggA appeared to be limited in total size. Continued growth most likely required disruption of the remaining free-monomer-like structure. AggA in Fig. 3.11 was modeled with swapping of structural elements. This type of interaction is possible because of the inherent self-complimentary nature of folded proteins. These interactions are also likely to sterically limit the maximum size of aggregates that could be so assembled.

3.4.3   Late lag phase aggregation loses calyx

During the late lag phase small aggregates were possible to image on the amino-silanized mica surface. In the DLS assay, the appearance of a wing on the distribution to larger R_H and the growth of a new feature at large R_H suggest aggregate growth resuming during this stage. The ThT assay shows a new pattern in the lifetime distribution. The ANS fingerprint analysis showed that AggB begins to get appreciable population while AggA decreases in population, suggesting a conversion from AggA to AggB. The ANS irreversibility assay showed that AggB had new binding sites for ANS. This suggested that the structural conversion was inside of the aggregate rather than a newly formed aggregate.

Conversion to AggB appeared to be required for growth to continue. The stability of AggB with respect to dissociation on the amino-silanized surface implied that it was more stable than AggA. AggB was larger, on average, than AggA. The monomer structure changed from AggA to AggB as reflected in the changes in the ANS assay binding sites. AggB was also structurally different than AggA in terms of the monomer-monomer interactions as suggested by the ANS reversibility assay. The changes in AggB structure allowed ThT-ThT interactions that were not possible in AggA. The ThT assay implied that some elements of the AggB structure might be similar to those in amyloid fibril. However, no fibrils or protofibrils were observed at this stage. The ThT lifetime contributions of fibrillar species were different than those of AggB. Conversion to AggB could be misinterpreted as amyloid formation if only changes in ThT intensity were measured.

3.4.4   Protofibrils appeared after day 20

During the growth phase the light scattering intensity increased enormously and the amount of large aggregate increased. AFM images showed the appearance of protofibrils followed by elongation of protofibrils and finally fibril assembly into long fibrils of varying length and diameter. The ANS assay showed dramatic growth in the protofibril fingerprint, a decrease in the AggA fingerprint, and a steady state for the AggB fingerprint. At very long incubation times very little ANS binding was observed to mature fibrils suggesting the presence of accessible hydrophobic regions on the protofibrils that disappeared upon formation of mature fibrils. We speculate that these hydrophobic locations are involved in the lateral association of protofibrils into fibrils. The ThT assay showed a new lifetime distribution pattern that continued to grow until at least day 34. We associated this pattern with amyloid protofibrils since the distribution was still very different than that observed from mature fibrils. Only some of the protofibril features were present in the ThT assay taken after 2 months of incubation where

mature fibrils were present. A large ThT lifetime contribution was present in the mature fibril data that was not present at any other stage. The structure of protofibrils must be different at the ThT binding level from that of fibrils.

3.4.5 Overall mechanism

The native β-strands in β-LGA are not in the right orientation to attain the cross-β geometry. It appears likely that an interaction analogous to domain swapping or opening of the β-sheet "sandwich" would be required for β-LGA to associate into the cross-β geometry. Based on the observed morphology of amyloid fibrils and the size of β-LGA, it would require approximately 2-3 β-LGA monomers, or 4-6 flattened monomers, to form the transverse structure of a 4-5 nm diameter fibril. A fibril of $\sim$45 nm in length would contain $\sim$32 β-LGA monomers and have a total molecular weight of 590 kDa. A fully formed amyloid fibril of 10 nm x 200 nm would contain $\sim$700 β-LGA monomers and have a total molecular weight of 12.9 MDa.

Our results suggest that there are two parts to the lag phase of βLGA amyloid formation. The sequence of events is similar to some recent kinetic analyses of amyloid nucleation.[22] We monitored the role of the hydrophobic core using the signature lifetime of ANS in the calyx. We showed how fluorescence lifetime fingerprints can be used to extract the contribution of multiple species during incubation. We identified two intermediates in the lag phase that are distinguishable by their relative stability, size, and binding of ThT and ANS. ANS is sensitive to the rigidity and polarity of binding locations, while ThT is sensitive to the relative geometry of its ThT binding sites. Based on this information, we must conclude that significant rearrangement of structure must occur between AggA and AggB. The standard interpretation of this change would be that AggB represents the conversion to the amyloid nucleus. However, ThT gave different signals when bound to AggA, AggB, and protofibrils. Moreover, the onset of

rapid growth of protofibrils does not occur until many days after the appearance of AggB. Therefore we must conclude that AggB is distinct in structure from both AggA and protofibrils. The presence of multiple aggregated species in a serial mechanism suggests that homogenous nucleation may not be a universal description of amyloid formation kinetics.

The initial aggregation into AggA and subsequent aggregation into AggB must have some driving force associated with them. Two simple models, colloidal aggregation and polymer phase stability, can be invoked to frame the initial aggregation. The inherent hydrophobicity of the polypeptide chain can lead to an aggregated phase of protein being more stable.[16] The driving force in this case is the increased number of favorable protein-protein and water-water contacts and a decreased number of protein-water contacts. Colloidal aggregation is similar except that it attributes the driving force to the partitioning of amino acids with unfavorable protein-water contact energies into a region of higher protein-protein contacts while amino acids with favorable protein-water contact energies are partitioned to the surface of the aggregate. This partitioning puts an additional geometric constraint on the aggregation process that is not present in the phase stability picture.

Given the large number of charged amino acids on βLGA we favor the colloidal aggregation picture, however our data only indirectly addresses this issue. Colloidal association in AggA and then AggB could reduce the barrier to the conformational change to cross-β required to form amyloid. Colloidal association is required because the monomer cannot rearrange without sacrificing a prohibitively large number of hydrophobic interactions. If the protein has a strong hydrophobic core, then the hydrophobic effect is too strong to disrupt. If the protein is completely unfolded the possible hydrophobic gains are too weak to overcome the translational entropy lost to aggregation.

There is a connection to protein folding in this analysis. Proteins below a

certain size typically cannot stably fold. This can be attributed to there not being a large enough number of favorable interactions to meet the thermodynamic conditions of cooperativity. By associating into colloidal or phase-separated aggregates, the protein increases its effective molecular weight and potential number of favorable interactions to the point where the fold of amyloid is accessible. This colloidal or phase-separated promotion of conformational rearrangement may explain the ability of surfactants to promote amyloid formation.

Amyloidogenic conditions have been identified for many non-disease-related proteins. This leads to the hypothesis that aggregation of proteins leading to amyloid fibril formation is a generic feature of polypeptides.[79, 7] If the hypothesis that amyloidogenesis is a generic possibility for proteins is valid, then we should think about amyloid as a particular state of protein in the polypeptide phase diagram. The driving forces for phase separation into amyloid should depend on the relative contributions of hydrogen bonding in the cross-β structure and the arrangement of hydrophobic groups. There is evidence that the polypeptide is hydrophobic from a polymer physics point of view, i.e. that polymer-polymer contacts are more energetically favorable than polymer-water contacts.[80, 81] This would suggest that the environmental and sequence determinants for amyloid propensity are more based on the lowering of the barrier to formation of the amyloid phase than on stability of the amyloid phase itself. In other words the effects are principally kinetic rather than thermodynamic. In particular in this study we propose that the initial aggregation to AggA allows a larger hydrophobic core to be formed in AggB. This allows the cross-β structure to be obtained in the protofibril. The initial bistability of the monomer allows formation of AggA. AggA allows a lower-barrier pathway to formation of AggB which is large enough to rearrange into the more stable cross-β structure without a prohibitively large activation barrier. This allows the spontaneous formation of amyloid protofibrils to occur even when barriers to formation of the cross-β structure directly from

the monomer or even AggA is energetically prohibitive.

3.5 Materials and Methods

3.5.1 Materials

Lyophilized β-LGA, thioflavin T, urea, APTES, sodium phosphate dibasic and mono-basic were purchased from Sigma. Fluorescence grade 8-anilino-1-naphthalenesulfonic acid ammonium salt (ANS) was purchased from Fluka.

A 10 mM sodium phosphate, pH 7.0 stock buffer solution was prepared with HPLC grade water. This buffer was used to prepare a second stock buffer containing 7.5 M urea. Both stock buffers were filtered through a 0.22 μm PES filter and stored at 4°C. For DLS measurements, extra care was taken to minimize scattering from dust contaminants by filtering stock buffer solutions with a pre-washed, 0.020 μm syringe filter (Whatman). The 0 M urea stock phosphate buffer was used to prepare a 138 μM stock protein solution of β-LGA and stored at 4°C. The protein stock solution was checked by UV absorption every few days to ensure its stability.

3.5.2 β-LGa incubations

We incubated β-LGA under conditions previously reported to show maximum amyloidogenicity[13] and aliquoted samples for time-resolved ANS and ThT luminescence, DLS, and AFM experiments.

For time-resolved luminescence and DLS measurements, 1.5 mL of protein sample for incubation was prepared every other day for 28 days and used for ANS assay along with the long-term DLS experiments. For ThT and ANS reversibility assay, samples were prepared every day for 34 days and 18 days, respectively. Each incubation sample was prepared by combining a 500 μL aliquot of the stock

protein solution to 1000 μL of the 7.5 M urea stock solution in a polypropylene eppendorf tube resulting in a final protein concentration of 46 μM and a final urea concentration of 5 M. The sample was capped, sealed with Parafilm, and placed in an incubator at 37°C. At the conclusion of the incubation, all samples were breached and each was parsed for contemporaneous experimentation.

To investigate the earliest aggregation with DLS, a sample of 46 μM β-LGA in 5 M urea, 10 mM sodium phosphate at pH 7.0 was prepared from the stock solutions above. The sample filled the cuvette to approximately 90% capacity in order to reduce the sample head space. Dynamic light scattering was measured while simultaneously incubated at 37°C in a Peltier sample chamber (instrumentation discussed below).

For the AFM measurements, lyophilized β-LGA was reconstituted and dialyzed against pre-filtered (0.22 μm) 100 mM phosphate buffer, pH 7.0. Prefiltered concentrated urea buffer was added resulting in a final sample condition for incubation of 50 μM protein in 5 M urea, 13.7 mM sodium phosphate at pH 7.0. The sample was incubated in a Parafilm-sealed 1.5 mL Eppendorf tube at 37°C over 65 days. The sample was inverted once each day that AFM was measured and 20 μL was aliquoted for the AFM image.

3.5.3 Time-resolved luminescence

Time-resolved luminescence was measured by time-correlated single photon counting (TCSPC). Experimental set up has been previously described[82] with the exception that the Spectra Physics Tsunami Ti:Sapphire laser was operated in femtosecond mode. All samples were analyzed at 37°C in a Quantum North-West TLC150 Peltier controller sample chamber (Spokane, WA).

For the ThT assay, a stock 5 μM ThT solution was prepared from the 0 M urea stock buffer. 50 μL of an incubated timepoint was aliquoted into 450 μL of ThT solution in a reduced volume cuvette and allowed to stand for 15 minutes

at 37°C. The excitation laser was tuned to 450 nm and the luminescence was observed at 482 nm. The time zero intensity ranged between 30,000 and 60,000 photons. A 50 ns collection window was used. Instrument response functions typically had a full-width at half-maximum (fwhm) of approximately 90 ps.

A 80 μM ANS stock solution was prepared in a 0 M urea stock buffer for the ANS assay. 500 μL of an incubated timepoint was combined with 10 μL of the ANS stock solution and allowed to stand for 15 minutes at 37°C.

For the ANS reversibility assay, a 1 μM ANS stock solution was prepared in a 0 M urea stock buffer. 50 μL of an incubated timepoint was combined with 450 μL of the ANS stock solution and allowed to stand for 15 minutes at 37°C. Excitation beam was tuned to 390 nm and the fluorescence emission was observed at 485 nm over a 100 and 82 ns collection windows for the ANS and ANS reversibility assays, respectively. A typical transient's time zero intensity was 4,000 for the ANS reversibility assay, whereas 18,000 photons was common for the ANS assay. Instrument response functions typically had a fwhm of approximately 100 ps.

We expect the population of the luminescent species to be piecewise continuous with respect to incubation time, making this system a prime candidate for global data analysis by the GIPG method.[63, 82]. ThT luminescence lifetime distributions were fit on an 80-point grid, logarithmically spaced in lifetime, ranging from 0.002 to 20 ns. Both types of ANS assays were fit on there own 58-point logarithmically spaced between ranging from 0.03 to 30 ns. A baseline and scattering term was included in the fits. To compensate for potential incident laser intensity fluctuations across incubation time, all TCSPC transients were normalized by the total time-zero photon population. This is accomplished by summing the parameters from a non-negative least squares fit [83, 63] The GIPG fits were considered statistically indistinguishable from the local fits by calculating the probability-to-reject [63, 84] to be less than 10^{-4} for all fits. ThT, ANS and ANS reversibility

assays GIPG fits used 8×10^5, 1×10^6, 1.5×10^6 iterations, respectively. The GIPG step scaling term referred to as λ, was set to 0.9.

3.5.4 Dynamic light scattering

Fluctuations of scattered light intensity were measured using a homodyne technique. At a particular incubation time, x, the intensity correlation function $g_2(t, x)$, was measured by a modified Nicomp Model 380 Particle Size Analyzer from Particle Sizing Systems. Scattered light from the incident laser, λ=532 nm, was collected orthogonally, θ=90°. The system employs a linearly-scaled 64-channel digital autocorrelator. For experiments completed in this paper, the native autocorrelator was bypassed by an ALV-6010 Multi-Tau autocorrelator (ALV-GmbH, Langen, Germany) for the maximum possible statistical accuracy across several orders of magnitude in decay time.[85]

Round borosilicate glass cuvettes (Kimble Glass) were used for all DLS measurements. In order to minimize dust contamination, each cuvette was rinsed with Millipore water. Cuvettes were placed in a micro-centrifuge, inverted (open-side face-down), then spun dry and stored face down. After sample was quickly and carefully added to the cuvette, it was covered with transparent tape to keep it dust-free, then wrapped in Parafilm for an additional seal.

For the 28 day DLS study, 250 μL of incubated sample was placed in a clean, dry cuvette. Twenty correlation functions were measured sequentially for 30 seconds apiece for each incubated sample. The cuvette chamber was held at a constant temperature of 37°C. For the continuous acquisition incubation, the same sample was analyzed every 15 minutes for 5 minutes at 37°C for 4.7 days.

The distribution of decay rates, $f(\Gamma, x)$, for particular incubation time point, x is related to the field correlation function, $g_1(t, x)$, by

$$g_1(t, x) = \int_0^\infty e^{-\Gamma t} f(\Gamma, x) \, d\Gamma, \tag{3.1}$$

where $f(\Gamma, x)$ can be solved for by the inverse Laplace transform. In most cases, the intensity and field correlation functions can be related via the Siegert relation, such that $\sqrt{g_2(t, x) - 1} \propto g_1(t, x)$.[85]

GIPG was originally demonstrated by globally fitting TCSPC transients, but it can be also employed to globally fit many types of spectroscopic data that require an inverse Laplace transform, such as in Eq. 3.1, as long as there is piecewise continuity in the experimental domain, x. One difference is that the intensity correlation functions do not require instrument-response convolution of the basis set. Another difference is that the standard deviations for the data were calculated in real time by the ALV-6010 correlator using a noise model.

DLS data was globally fit on a 50-point grid of logarithmically-spaced decay times, Γ^{-1}, ranging from 0.001 to 65 ms. A baseline term was included. The total number of correlation functions used in the short-term DLS fit was reduced 340 to 34 by averaging every ten correlation functions into a single trace and propagating the error accordingly. The probability-to-reject the GIPG solution for both data sets was less than 10^{-4}.

In DLS, a particle's decaytime is related to the translational diffusion constant though the scattering vector, q, such that $D = \Gamma/q^2$, where $q = 4n\pi/\lambda \sin(\theta/2)$, where n is the refractive index. The diffusion constant can then be converted to Stokes-hydrodynamic radius (R_H) using the Stokes-Einstein relation, $R_H = (k_bT)/(6\pi\eta_0 D)$, assuming a spherical shape. For these experiments, T is the temperature, η_0 is the viscosity of the buffer, and k_b is the Boltzmann constant. The characteristic density of the partially unfolded monomer determined from assignment of a urea titration DLS experiment at 5.0 M was used to scale the oligomer sizes.

3.5.5   Atomic force microscopy

To obtain better adhesion of protein aggregates to a mica surface, a chemical surface modification was implemented. 20 uL of 0.1 (V/V) APTES (Aminopropyl-triethoxysilane) was applied evenly on freshly cleaved 9.9 mm diameter mica disk. After 10 minutes unreacted APTES was rinsed away with 15 mL 0.2 μM filtered deionized water. The surface was blown dry with high purity compressed nitrogen gas. Incubated sample was applied evenly on freshly prepared surface for 10 minutes. Unbound species were rinsed away with Millipore water. The sample was again dried with nitrogen gas before being imaged with a MultiMode Scanning Probe Microscope (Digital Instruments) with a TESP tip in tapping mode.

Chapter 4

Exploring αSyn with covalently attached fluorophores using time-resolved and single molecule imaging spectroscopy

4.1 Summary

In recent years, time-resolved fluorescence techniques have become very useful for elucidating a host of biophysical problems. Using conformationally sensitive fluorescent probes allows the differentiation of local environments and the ability to infer conformational changes in the host molecule. The downside is that multiple lifetimes acquired for a single system can be complicated to understand. We take two approaches to solve this: global analysis of bulk data and utilizing single molecule imaging spectroscopy. The first approach can be accomplished by acquiring data transients while simultaneously, but smoothly, perturbing an experimental coordinate, such as temperature, wavelength, denaturant concentration, etc. It is then applicable to utilize the globally regularized interior point gradient method to determine the lifetime components of the system without the need to a specify a model *a priori* (see Chap. 2 for details). [1] In the second approach, we can avoid the ensemble averaging present in all bulk experiments by employing single molecule lifetime imaging [2] to identify characteristic lifetimes species-by-species.
Figure 4.1: *The number of publications between the years 1962 to 2007, with the concepts of fluorescence, lifetimes and protein.* The importance of time-resolved fluorescence has grown substantially in recent years. Information was provided by the Chemical Abstract Service.

4.2   Introduction

Time-resolved fluorescence (TRF) and single molecule fluorescence techniques have become an important contributors to the field of biophysics. [3] They have been the beneficiaries of critical advances during the last 25 years in molecular biology (such as polymerase chain reaction), laser technology (tunable and pulsed) and detection systems (microchannel plates and fast avalanche photodiodes). [4] These advances allow for practical, biologically relevant research.

Using fluorescence to monitor biological systems has several advantages. First, fluorescence spectroscopy is sensitive because it is (usually) trivial to separate the background from signal. If necessary, measurements can be made at picomolar concentrations. Second, the amount of time spent in the excited state is usually on the order of several nanoseconds. From a protein folding point-of-view, this is the optimal timescale for investigating secondary and tertiary structural changes. [4, 5] A few nanoseconds in the excited state is a sufficient amount of time for a probe to become in contact with a quencher, diffuse, reorientate, and/or form transient complexes with the solvent. All of these environmental factors can modulate the fluorescence properties. The goal is to connect the spectral observable with the

molecular features of the system.

In this chapter, we evaluate the fluorescence properties of three different covalently attached fluorophores to α-synuclein (αSyn) using time-correlated single-photon counting (TCSPC). αSyn is an intrinsically disordered protein (IDP) [6] found in the brain. αSyn aggregates into highly structured pathogenic fibrils and is implicated in Parkinson's Disease. [7, 8]

Time-averaged, or steady-state, fluorescence measurements fall quantitatively short of reporting on the multi-state properties of the system. [4] Only by measuring fluorescence lifetimes can the separate components of the intensity signal be ascertained. In chapter 3, we showed the power of elucidating the evolution lifetime distribution of an environmentally-sensitive, non-covalently attached probe in order to determine aggregation states of β-lactoglobulin A. [9]

The lifetime distribution of a covalently attached fluorophore can report environmental changes undergone by αSyn along an experimental coordinate (temperature, incubation time, etc.). However, as the number of environments increases, the lifetime analysis can become unstable. In chapter 2, we combat this issue by applying a novel global analysis method to stabilize lifetime fitting called globally regularized interior point gradient method (GIPG). [1]

Single molecule fluorescence imaging of aggregates with covalently attached fluorophores can be utilized to elucidate the lifetime components on a species-by-species basis. To differentiate between monomers, aggregates and fibrils, several images are taken. With each pass, species photobleach. Monomers are expected to be dim and photobleach easily in just a few image passes. Oligomers will stepwise lose intensity as the dye is bleached. Fibrils are expected to have at least two defining features: high intensity and several hundred nanometers long or more. By keeping track of photobleaching steps for any aggregate, it is possible to calculate the number of monomers per aggregate [10].

Nile Red (NR) is a solvatochromic dye. The emission of NR is red-shifted

in polar environments. By non-covalent intercalation, NR has been used to probe hydrophobic protein surfaces [11], membrane interfaces [12], and polymer matrices on a single molecule level [13]. Covalent attachment of NR via an aliphatic linker was used to study the environmental changes in a bacterial chaperonin with its cofactor [14]. By covalently attaching NR to a cysteine mutant of human αSyn (A19C), we plan on measuring bulk and single molecule fluorescence lifetimes to monitor conformational changes along αSyn self-assembly leading to amyloid formation.

The chromophores Atto 590 (Atto) and Alexa Fluor 488 (Alexa) are considered conjugation candidates for studying αSyn aggregation via TRF techniques. These experiments include a full incubation of Alexa-αSyn or Atto-αSyn conjugate with lifetime analysis, similar to that completed in Chap. 3. Also considered is a co-incubation fluorescence resonance energy transfer (FRET) experiment study described in more detail in Chap. 6. A cysteine conjugate of Alexa (Alexa-cys) also is prepared as a control for the possible quenching of Alexa-αSyn with the amino acid side chains.

Property	Alexa 488	Atto 590
τ / ns	4.1	3.7
τ_n /ns	4.7	4.2
CF_{260}	?	0.42
CF_{280}	0.10	0.44
ϵ_{max}	72,000	120,000
λ / nm	493	594
Supplier	Atto-Tec	Invitrogen
Price / $	188	400
A_{493}	1	0.04

Table 4.1: *Physical properties and other information concerning Alexa 488 and Atto 590.* τ is the lifetime, τ_n is the calculated natural lifetime, CF_{280} is the correction factor at 280 nm, or A_{280} divided by the absorption at maximum, CF_{260} is the same as CF_{280} but at A_{280}, ϵ_{max} extinction coefficient, λ is wavelength at absorption maximum, A_{493} is relative to the Atto absorption at 493 nm.
Figure 4.2: *Structures of the fluorophores featured in this chapter. A) Alexa Fluor 488, B) Atto 590 and C) Nile Red.*

4.3 Methods

4.3.1 Selected materials

Atto 590 C5 maleimide was purchased from Atto-Tec (GmbH) and Alexa Fluor 488 C5 maleimide from Invitrogen (Carlsbad, CA). TCEP (tris-(2-carboxyethyl)phosphine) was also purchased from Invitrogen. Nile Red maleimide was generously donated by Professor W. E. Moerner (Stanford University). Cysteine was purchased from Sigma-Aldrich (St. Louis, MO).

Protein Preparation

Escherichia coli BL21 DE3 strain (Invitrogen Inc.) were transfected by plasmids (pT7-7) encoded human αSyn A19C mutant and were gifts from Professor Jean

Baum (Rutgers University). Expression and purification of mutant αSyn followed published protocols. [15]

4.3.2   Protein conjugation

Invitrogen's protocol for thio-reactive probes was followed for the protein conjugation of NR-αSyn, Alexa-αSyn and Atto-αSyn. We note several changes/preferences. Buffer used 10 mM phosphate, pH 7.0. Dyes were dissolved in 50 μL, or less, of DMSO. TCEP was used to reduce disulfide bonds. Bio-Gel P-10 (BioRad) columns were used for removing unreacted dye. β-mercaptoethanol was used to stop the reaction. Alexa-αSyn and Atto-αSyn were filtered through a 100 kDa molecular weight cutoff filter prior to experiments. Final concentrations were about 1 mg/mL.

4.3.3   Cysteine conjugation

Along with the above protocol alterations, Alexa/cysteine conjugation requires special attention to remove excess reactants. For this reaction, a 10X molar excess of cysteine to Alexa maleimide was used. Removal of free cysteine was performed by dialyzing against buffer with a low binding 500 Da cutoff Spectra/Por CE dialysis bag.

4.3.4   Fluorescence spectroscopy

Temperature steady-state emission spectra were taken on a Cary Eclipse spectrometer (Varian Inc.). Excitation was set to 493 nm, and emission was 505 to 600 nm. Slit widths were set to 5 nm.

Data was taken every 5 C^o from 5 to 95 $^\circ$C, then back to 5 $^\circ$C at a rate of 1 C^o/min.

Time-resolved fluorescence

TRF was measured by TCSPC. For NR-αSyn, the experimental set up has been previously described [10]. Temperature was maintained by a Quantum North-West TLC150 Peltier controller sample chamber (Spokane, WA). Three experiments were performed by the NR-αSyn conjugate. First, emission lifetime was monitored at nine different wavelengths (ranging from 635 to 715 nm) with a 10 nm slit while held at 37 °C. Then NR emission was measured at 655 nm as the temperature was increased. The experiment was repeated but observing at 690 nm. Temperatures used were 15, 25, 37, 50, and 75 °C.

For Alexa-cys, Alexa-αSyn and Atto-αSyn conjugates, experimental setup was the same except that the Spectra Physics Tsunami Ti:Sapphire laser was operated in femtosecond mode. The laser was tuned to 450 nm (after frequency doubling) for the Alexa-cys and Alexa-αSyn experiments. Alexa-cys emission was monitored at 516 nm with a 10 nm slit at 15, 25, 37, 50, and 75 °C. The emission for the Alexa-αSyn was collected in similar fashion, except that temperatures ranged from 5 to 85 °C, every ten degrees.

The absorption maximum of Atto-αSyn is at 593 nm and is well outside the tunable range of the mid-range (M) optics set. Instead, a 400 nm excitation beam was used where there is a small absorption band, most likely the second excited state S_2. We assume that excitation into this band will result in a fast relaxation process (tens of femtoseconds, perhaps) to the first excited state, S_1, then radiatively emit back to the ground state, S_0. Emission was monitored at 635 nm with a 10 nm slit and ranged from 10 to 90 °C, every ten degrees.

Single molecule imaging

Two NR-αSyn samples were prepared for imaging: time-zero and after 8 days of incubation at 37 °C. These samples were diluted to 100 pM, and 20 μL of sample

was placed on a glass slide cleaned with strong acid and base. Experimental setup for acquiring images was described in Ref. [10]. After drying, an 8×8 μm area of slide was imaged.

4.3.5   Data analysis

Globally regularized IPG method (GIPG) was implemented as the analysis tool for all bulk lifetime measurements using a second derivative continuity condition. [1] All data was fit on a 99-point, linear-spaced lifetime grid ranging from 0.1 to 10 ns with 500,000 iterations and a step parameter of 0.9. Probability-to-reject for all fits were less than 0.01 (as compared to an Active Set fit). Lifetime analysis of single molecule images were calculated by Becker-Hickl SPCM software (as part of the Becker-Hickl SPC-630 correlator board).

4.4   Results and Discussion

4.4.1   Properties of Alexa 488
Figure 4.3: *Steady-state emission spectra versus temperature.* Left panel: steady-state emission at the start, middle and end of temperature cycle. The spectrum exhibits typical thermal broadening at high temperatures, but is reversible after the completion of the cycle. Right panel: a contour plot of the evolving emission spectra across the temperature cycle. There is slight loss of signal as the sample returns to back 5 °C and suggests irreversible fluorescence quenching.

Steady-state fluorescence emission spectra of Alexa-αSyn broadens with temperature, but the shape is reversible when returning to low temperatures as shown in the right panel of Fig. 4.3. The overall intensity of the peak maximum decreases with increasing temperature and increases with decreasing temperature. This feature is consistent with a temperature-dependent quenching mechanism. However, there is an overall intensity loss while cycling from low to high and back to low temperature suggesting a quenching mechanism has become irreversible. We expect that this feature is the consequence of protein aggregation as shown by dynamic light scattering data (shown in Chap. 5).
Figure 4.4: *Lifetime dependence of temperature of Alexa-αSyn conjugate.* The main 4.1-ns component does not shift with temperature, but there is a small contribution from a 800-ps species that appears as the temperature increases. Both features are marked with circles and will be referred to later in the text when describing the Alexa-αSyn conjugate lifetime evolution. Reduced chi-square of the fit is 1.19.

Measuring the fluorescence lifetime properties of Alexa-cys conjugate is a control for the Alexa-αSyn experiments. From 15 to 75 °C there is no significant change in the lifetime distributions as shown in Fig. 4.4. There is a fast 800-ps component that appears at the high temperatures but is only 1% of the total
Figure 4.5: *Lifetime dependence of temperature of Alexa-αSyn conjugate.* Two new features, marked by squares at 1.1 and 3.4 ns appear as the temperature increases. The Alexa-cys control is marked by circles. Reduced chi-square of the fit is 1.11.

fluorescence. The majority feature is a 4.1 ns component and does not change with temperature. In Fig. 4.4, we detail these features in the control with circles.

Fig. 4.5 shows the lifetime distribution of Alexa-αSyn evolving with temperature. At low temperatures, the amplitude of the long lifetime is slightly shifted to 4.3 ns as compared to the control. As the temperature increases to about 65 °C, the amplitude decreases substantially while a new feature at 3.4 ns appears. Also, a shorter 1.1 ns component begins to show significant population that is not present in the control. We designate these different features with squares. As in the control, the 900-ps feature is present at high temperatures.

Interpretation

The decrease in intensity is due to the loss of the 4.3 ns species. As the temperature increases, two new short lifetimes appear in the protein conjugate that does not appear in the control (squares versus circles) suggesting that quenching may be related to contact with the polypeptide side chains. If the quenching is due to

amino acid interactions, aggregation may enhance this effect. By utilizing TRF, Alexa is a potential fluorescent probe candidate for monitoring the intermediate species during protein aggregation.

4.4.2 Properties of Atto 590
Figure 4.6: *Lifetime dependence of wavelength of Atto-αSyn conjugate at* 37 °C. As the temperature increases, we expect a slight shift to shorter lifetimes as potential pathways out of the excited state increase. Reduced chi-square is 1.17

The Atto-αSyn is fairly consistent in terms of lifetime in range of temperatures tested. There is a small shift from 4.4 ns to 4.1 ns with increasing temperature. By 65 °C, a minority 600 ps component appears. Finding a probe with fluorescence properties that do not modulate with temperature (and possibly aggregation) is advantageous for FRET experiments. Because the properties do not change with conditions, changes in signal will be purely dictated by the FRET properties.

Interpretation

Alexa and Atto fluorophores were considered candidates FRET measurements such as in the experiments described in Chap. 6. Since the monomer hydrodynamic radius of αSyn is about 3.3 nm, as measured in Chaps. 5 and 6, an

Alexa-αSyn /Atto-αSyn dimer should allow energy transfer. We have identified at least one potential problem with a FRET experiment that must be considered: the lifetime of Alexa-αSyn conjugate has a temperature dependence. Fortunately, at 37 °C majority of the Alexa conjugate fluorescence has a 4.3 ns lifetime.
Figure 4.7: *Absorption and emission spectra for Alexa 488 and Atto 590.*

4.4.3   Properties of NR-αSyn

The lifetime evolution along the emission band of NR-αSyn helps to identify different local environments NR is experiencing. A 1.7 ns species, designated by a pentagon, provides the majority population. This feature does change much over the emission band from 635 to 715 nm. A feature at 4.0 ns shifts to 3.8 ns and narrows while moving to the red wavelengths. We note the two lifetimes which change considerably across the experimental coordinate. First is a 350 ps, that only exists at wavelengths less than 660 nm emission. The second is a species that begins to grow in at 900 ps starting at 635 nm and increases in population with redder emission. These two features, marked with a diamond and triangle, have the most potential to report the local environments of NR.

At 655 nm at low temperatures, three main components exist: 350 ps (diamond), 1.3 ns (pentagon) and 3.3 ns. The most populated species shifts from 1.3 to 1.1 ns as the temperature increases, but this shift may be partially due to a
Figure 4.8: *Lifetime dependence of wavelength of αSyn-NR conjugate at* 37 °C. By scanning over emission wavelengths, local polarity environments are probed. At blue emission the local environment of NR is less polar than at red emission. We draw attention to features that change with wavelength and overlap at 655 nm: the 350 ns feature with diamonds and the 900 ps feature with triangles. Pentagons represents a species that does not have significant changes with wavelength.

fitting artifact to be explained later. The 350 ps component, however, converts to a new species at about 420 ps. The 3.3 ns is a minority component that is lost at higher temperature. At the 45 °C, a 900 ps feature appears (triangle).

The 900-ps and 1.7-ns features shift slightly in the 690-nm lifetime distributions. A 4.0-ns species, which was fairly intense in the emission sweep (Fig. 4.8), is much less intense then expected. This species shifts and disappears as the temperature increases.

Interpretation

There are several features present in the lifetime distributions shown, however, we will focus on the few that dynamically change along our experimental coordinates. Further interpretation of the data would require more control experiments (i.e. higher temperature data, and or measuring NR-cys conjugates).
Figure 4.9: *Lifetime temperature dependence of αSyn-NR conjugate at 655 nm emission.* At 655 nm emission, NR should be reporting a mixture of from polar and non-polar environments. 350 ps feature shifts (diamonds) to longer decay times where as the 1.7 ns feature (pentagons) shifts to shorter decay times. There is also 900 ps component (triangles) at highest temperature measured.

A 900 ps lifetime feature appears in the red-edge emission, suggesting this lifetime reflects NR in a polar environment (triangle in Fig. 4.8). The short 350 nm feature exists only in the blue-edge emission, and therefore reflects NR in a less-polar environment (diamond in Fig. 4.8). The short lifetimes may be indicative of NR protein interactions and/or amino acid quenching.

Observing fluorescence emission at 655 nm should reflect both hydrophobic and hydrophillic environments of NR (Fig. 4.9). Since NR is a hydrophobic fluorophore, it is reasonable to hypothesize that there are greater driving forces for interacting with non-polar amino acids than with the solvent. We expect that increasing the temperature will balance the forces and allow NR to experience more time in the solvent. As the temperature increases to 35 °C, the 350-ps feature shifts to 420 ps, consistent with less interactions amino acids residues. A 900 ps species is replaced by a 1.3-ns feature present at low temperatures and shifts to 1.1 ns at 45 °C. This may be the product of a fitting artifact.
Figure 4.10: *Lifetime temperature dependence of αSyn-NR conjugate at 690 nm emission.* At 690 nm emission, NR should be reporting from a polar environment. As the temperature decreases, there are slight shifts in the 900 ps feature (triangle) and the 1.7 ns feature (pentagons) to longer decay times. A long lifetime component (4.0 ns) disappears with increasing temperature.

From the wavelength dependence fit (Fig. 4.8), there are two clearly separable populations present (900 ps and 1.7 ns) demonstrating the utility of the GIPG fitting technique. However, less data and more subtle changes in the temperature dependent lifetime distributions at 655 nm (Fig. 4.9) make differentiating between sub-populations difficult. Therefore, 1.3 ns species is most likely to be a combination of the 900 ps and 1.7 ns features, and shifts to 1.1 ns when the 900 ps species dominates. Notice a 900-ps species gains population at this high temperature. If the temperature course were extended, this fitting artifact would not be an issue.

It must be noted that because NR is hydrophobic, NR conjugates may induce a collapsing mechanism. [16] This is especially true because αSyn is an IDP. Temperature dependence lifetime changes may be indicative of the driving forces of NR to be buried within hydrophobic sections of the protein. Therefore, as with any experiment that uses extrinsic labeling, a control for protein aggregation must

be performed on the wild type protein with an independent measure of amyloid growth.

4.4.4 SM

Single molecule imaging allows the separation of lifetimes of different sized NR-αSyn aggregates found in the bulk solution. Monitoring the discrete drops in intensity of an imaged particle for each successive scan, it is possible to identify the number of probes per spot. Coupled with lifetime analysis, a lifetime can be designated for a particular size or type of aggregate. [10].

The single molecule images shown in Figs. 4.11 and 4.12 are of time-zero and day 8 NR-αSyn, respectively, and is colored by lifetime. In panel A, there are several spots with lifetimes ranging from 2 to 4 ns. After a second scan (panel B), several of these features go dark including the one inside the circle. Panel C represents a third pass; most of the fluorescence has disappeared except for the blue spot (4 to 6 ns) in the white box. Panel D reveals recovery by some molecules (for example, on the far left), but the blue spot has almost disappeared. After 8 days of incubation, fibrils have formed as determined by atomic force microscopy (data not shown). Typical fluorescence of a fibril is shown in Fig. 4.12. The lifetime for a fibril is consistently short, i.e. 0.4 to 1.0 ns.

Interpretation

Monomers, aggregates, and fibrils can be distinguished by their NR lifetimes using single molecule fluorescence. Features with similar low intensity and photobleach by scan B, such as in the white circle shown panel A to B in Fig. 4.11, suggest these molecules are monomeric NR-αSyn. The lifetime for the monomer ranges from 2 to 4 ns suggesting the environment allows the non-polar regions of protein to be available to NR even though it is partially exposed. Oligomers are round and amorphous, take multiple steps to photobleach, and exhibit longer lifetimes
Figure 4.11: *Single molecule images of NR-αSyn monomers and aggregates colored by lifetime.* By performing several scans, single particles will photobleach. Particles that photobeach in a single step are speculated to be single NR-αSyn molecules. Multiple photobleaching steps, or descrete intensity drops, suggest aggregates species. Lifetimes of the particles are simultaneously measured and therefore it is possible to correlate a lifetime to species size. The same image field was taken in four consecutive scans A through D.

ranging from 4 to 6 ns. Unstructured aggregation of proteins allows more polar regions of the protein to be available to NR and reduces exposure to solvent. Conversely, amyloid fibrils are highly structured in cross-β formation. There are many photobleaching steps needed because of large numbers of proteins forming the fibril. The organization of proteins in fibrils forces more exposure of NR to solvent, reducing fluorescent lifetime.
Figure 4.12: *An αSyn fibril with covalently attached NR.* The lifetime of a fibril is very short compared to the monomeric conjugate.

4.5 Conclusions

TRF measurements of covalently labeled αSyn can be used to qualitatively identify conformational states of intermediate species during a protein aggregation. There also is promise that Alexa and Atto dyes can be used for future FRET measurements. Based on bulk and single molecule lifetime images, NR may have proven that it can be effectively used as a probe to identify intermediate species along the amyloid formation pathway. However, we need to be prudent and realize that extrinsic labeling may affect the protein aggregation mechanism, making it necessary to conduct independent control experiments.

Chapter 5

Thermodynamic studies of α-synuclein

5.1 Summary

α-Synuclein is an intrinsically disordered protein found in the brain and is implicated in Parkinson's disease. It has no known function but its primary sequence is highly conserved across species. Understanding its monomeric conformational properties may led to elucidating its function. Little has been published on the thermodynamic states of α-synuclein. We show that there are subtle spectroscopic transitions present in the ellipticity and 287 nm absorption. The spectroscopic transitions are connected to the microscopic states of the system through the partition function. We take advantage of the partition function to calculate the temperature at which a transition occurs and speculate how these transitions relate to secondary and tertiary conformational changes.

5.2 Introduction

Disease

Parkinson's disease (PD) affects over half-a-million people in the the United States. [1] Clinical symptoms of PD include characteristic resting tremors and inability to control the extent of their movements. α-Synuclein (αSyn) is the main component of the intracytoplasmic proteinaceous deposits found in the brains of 70 to 80% of patients clinically diagnosed with PD. [1]. Neuronal inclusion bodies, called Lewy bodies, contain aggregated αSyn in the form of fibrils which exhibit

cross-β quaternary structure. However, pathological implications of Lewy bodies have been questioned and has led to research on the pre-fibrillar oligomeric aggregation states of αSyn. [2, 3, 1] One of the interesting features of αSyn is that it belongs to a class of protein that is intrinsically disordered. In an intrinsically disordered protein, or IDP, there is no evidence of a single native structure. Studying the aggregation mechanism of αSyn begins with a basic understanding of the properties of the monomeric protein.

Intrinsically disordered protein

IDPs can be characterized by using X-ray crystallography, NMR spectroscopy, circular dichroism spectroscopy, protease digestion, and hydrodynamic radius determination. Researchers using X-ray crystallography were the first to discover there were *segments* of a protein that had indiscernible structure but were absolutely necessary for function. [4] Because of the dynamic nature of NMR, it since become a powerful technique in recognizing segmental conformational ambiguity. [5]

The structure-function paradigm has become a cornerstone of protein structure prediction and structural genomics. [4] The relationship between primary sequence $\rightarrow$ 3 dimensional structure $\rightarrow$ function has helped structural biologists to understand features of protein when one or two parts are unknown. However, the obvious prerequisite is that the protein has to have either a function or a native structure to be useful in this paradigm.

The function of αSyn in the brain is poorly understood [2, 1], but it is known that the expression levels in the brain are high [6], and it is highly conserved across species. [7] We presently aware of only two thermodynamic studies of αSyn but they were conducted in the presence of sodium dodecyl sulfate [8] and phospholipid vesicles. [9] Remeta and Minetti have recently conducted differential scanning calorimetry experiment at high concentrations of αSyn, but have not seen

any sign of an enthalpic transition. (personal communication).

Two thermodynamic states

Two-state transitions are often used to describe protein folding mechanisms when no intermediate species are observed. Observing versus not observing intermediates when these species *do* exist may be the consequence of several factors. For example, the experimental timescale needs to be comparable to the lifetime of species. Also, the signal needs to be sensitive to intermediate species. Ensemble averaging of the signal adds another confounding complication to the differentiating intermediate species. Single molecule spectroscopy has been used to circumvent the last condition. [10, 11, 12] Discussions concerning protein folding transitions are described in detail elsewhere. [13, 14, 15, 16].

Since αSyn has very little intrinsic structure, the classic folding paradigm innately does not apply. However, when αSyn is heated, certain spectroscopic observables modulate. A simple way to describe the change in the observable is to consider the protein is moving from one thermodynamic state to another. This is in spite of not having a single native state conformation. Moving from an intrinsically disordered to state to an even greater, or extrinsically, disordered state, there are low expectations for a large observable transition. Because of this the nuances of the transitions are not explicitly discussed here.

The partition function connects the macroscopic thermodynamic properties with the microscopic states. The partition function can then be formulated such that the multiplicity of the upper state and the energy gap are parameters which fit the spectroscopic observables. If the data supports greater degeneracy in the upper state, this suggests a more cooperative transition. The energy and the "cooperativity" parameters can be used to predict the transition temperature, T_m, as the system moves from one spectroscopic state to another.

Three biophysical techniques are used to monitor the thermodynamics of

αSyn. Circular dichroism (CD) is utilized to monitor the evolution of mean residue molar ellipticity and give clues of overall secondary structure changes. Dynamic light scattering (DLS) is used to follow the average change in hydrodynamic radius (R_H). Lastly, modulation in the ultraviolet absorption (UV) at 287 nm is often indicative of some tertiary structural changes of the tyrosyl moieties. [17] UV measurements in this range can be confounded by absorption overlap with tryptophan; fortunately, αSyn does not have tryptophan in its primary sequence. These techniques may lay down the ground work for future more complicated experiments, such as NMR and computer simulations, which can theoretically yield information on a residue-by-residue basis.

5.3 Methods

5.3.1 Preparation and Purification

Escherichia coli BL21 DE3 strain (Invitrogen Inc.) were transfected by plasmids (pT7-7) encoded human αSyn and was a gift from Professor Jean Baum (Rutgers University, Piscataway, NJ). Expression and purification followed published protocols. [18] αSyn was lyophilized and stored until it was reconstituted to 1.0 mg/mL in 10 mM phosphate, pH 7.0 buffer at the time of the experiment. To remove the insoluble and soluble aggregates from protein solution for any experiment, the sample was filtered through a Microcon 100 kDa molecular weight cutoff filter (YM-100, Millipore).

5.3.2 UV

Temperature-dependent UV melting experiments were performed on an Aviv Model 14 UV/Vis spectrophotometer (Aviv Biomedical Inc., Lakewood, NJ). Samples in quartz cuvettes of 1.0 cm pathlength were heated in the thermostatted

sample compartment over the temperature range of 0 to 100 °C. The absorbance at 287 nm was recorded at 0.5 C^o increments following integration for 10 seconds to monitor the absorbance changes as a function of temperature. Though a preliminary melt on the VARIAN was performed at 250, 280, 287, and 350 nm, only the 287 nm absorption had a visible transition.

5.3.3 DLS

Round borosilicate glass cuvettes (Kimble Glass) were for the DLS measurement. In order to minimize dust contamination, the cuvette was rinsed with Millipore water. It was then placed in a micro-centrifuge, inverted (open-side face-down), then spun dry and stored face down. After the sample was quickly and carefully added to the cuvette, it was covered with transparent tape to keep it dust-free, then wrapped in Parafilm for an additional seal.

Fluctuations of scattered light intensity were measured using a homodyne technique. At a particular temperature, T, the intensity correlation function $g_2(t, T)$, was measured by a modified Nicomp Model 380 Particle Size Analyzer from Particle Sizing Systems. Scattered light from the incident laser, λ=532 nm, was collected orthogonally, θ=90°. The system employs a linearly-scaled 64-channel digital autocorrelator. The native autocorrelator was bypassed by an ALV-6010 Multi-Tau autocorrelator (ALV-GmbH, Langen, Germany) for the maximum possible statistical accuracy across several orders of magnitude in decay time. [19]

DLS correlation functions were fit using regularized GIPG with a linear continuity condition. [20] The Laplace transform was performed using a grid of exponential decay times. A particle's decay time is related to the translational diffusion constant though the scattering vector, q, such that $D = \Gamma/q^2$, where $q = 4n\pi/\lambda \sin(\theta/2)$, n is the refractive index. The diffusion constant can then be converted to a Stokes-hydrodynamic radius (R_H) using the Stokes-Einstein

relation, $R_H = (k_b T)/(6\pi\eta_0 D)$, assuming a spherical shape of the monomer. For these experiments, T is the temperature, η_0 is the viscosity of the buffer, and k_b is the Boltzmann constant. Changing the temperature will not only affect the conversion of D to R_H, but also there is a temperature dependence of n and η_0. Properties of water were provided by the Ref. [21] and were considered for the conversion.

The 116-point grid was composed with a varying density of decay times to maximize the regions of Laplace space that would represent the monomer accurately. In order to have true continuity, the grid of decay times were shifted with respect to continuity in R_H from temperature to temperature. The decay grid was logarithmically spaced in equivalent R_H from approximately 0.1 to 2.0 nm (15-points), linearly spaced from 2.0 to 6.0 nm (41-points), and the remaining logarithmically spaced to 10^6 nm. The resulting GIPG parameters that represent R_H between 2.0 and 6.0 nm were fit to a normal distribution in order to identify the mean radius for the monomer only.

5.3.4 CD

Circular dichroism spectra were recorded on an AVIV model 400 circular dichroism spectrophotometer (AVIV Biomedical, Lakewood, NJ, USA) equipped with a programmable thermoelectrically controlled sample compartment. The thermal stability of αSyn secondary structure was monitored by heating samples containing 25.0 μM (362.32 μg/mL) protein at a programmed rate of 60 deg h^{-1} over the range of 0 to 100 °C in a 0.1 cm quartz cuvette. The ellipticity was recorded at 0.1 C° intervals employing a time constant (integration period) of 6 s to generate temperature-dependent circular dichroism profiles at 222 nm and 198 nm. The data was normalized and plotted in units of mean residue molar ellipticity

$([\Theta]_{\mathrm{m}rw,\lambda})$ according to the following relation:

$$[\Theta]_{\mathrm{MRW},\lambda} = \frac{(\mathrm{MRW})\Theta_\lambda}{10dc} \tag{5.1}$$

where Θ_λ is the observed ellipticity (degrees) at wavelength λ, d is the cuvette pathlength (cm), and c is the protein concentration (g mL^{-1}). MRW is the Mean Residue Weight of the peptide bond as calculated from the relation:

$$\mathrm{MRW} = \mathrm{M}_W(N-1)^{-1} \tag{5.2}$$

where M_W is the molecular mass (Da) of the polypeptide chain, N is the number of amino acids in the chain, and $N-1$ is the number of peptide bonds in the chain. In the specific case of αSyn, M_W is 14,460.1 Da and N is 140 residues. Substituting these relevant parameters into Eq. 5.2, a Mean Residue Weight of 104.03 Da is calculated for αSyn. The mean residue molar ellipticity ($[\Theta]_{\mathrm{MRW},\lambda}$) of αSyn is determined by normalizing the observed ellipticity at 222 nm (Θ_{222}) or 198 nm (Θ_{198}) with the relevant parameters of MRW (104.03 Da), d (0.1 cm), and c (362.32×10^{-6}g mL^{-1}) in Eq. 5.1. The units of mean residue molar ellipticity are deg cm^2 dmol^{-1}.

5.3.5   Two-state model

The partition function connects the macroscopic thermodynamic properties with the microscopic states. We can use the partition function to specify how the different structures are partition throughout all accessible states. For a two-state model, let us consider a ground (energy is set to zero, or $\epsilon_0 = 0$) and one excite macrostate, ϵ, comprised of γ microstates. By adding a factor of γ degeneracy to the excited state, the entropy of the upper state is greater. The partition function is then,

$$Q = 1e^{-0/RT} + \gamma e^{\epsilon/RT}. \tag{5.3}$$

The probability of being in the ground state or excited state is therefore $(1 + \gamma e^{\epsilon/RT})^{-1}$ or $\gamma e^{\epsilon/RT}(1 + \gamma e^{\epsilon/RT})^{-1}$, respectively. The observed signal is the expectation value of the signals coming from the ground and excited states,

$$S(T) = O_0 \left(\frac{1}{1 + \gamma e^{-\epsilon/RT}} \right) + O_1 \left(\frac{\gamma e^{-\epsilon/RT}}{1 + \gamma e^{-\epsilon/RT}} \right). \qquad (5.4)$$

where O_0 and O_1 are representative of the pure macrostate observables of ground and excited states, respectively. R is the gas constant and T is in Kelvin. For CD data, two observables were monitored and were globally fit with ϵ and γ as global parameters. O_0 and O_1 represent the local parameters for ellipticity at 222 nm, and O_0' and O_1' are the local parameters for 198 nm.

The temperature at which the transition occurs can therefore be calculated by,

$$T_m = \frac{\epsilon}{R \ln(\gamma)}. \qquad (5.5)$$

All data was fit with Eq. 5.4 using nonlinear least-squares fitting by implementing IGOR's Levenberg-Marquardt curvefit package.

5.4 Results

5.4.1 UV

Fig. 5.1 demonstrates how the UV absorption changes in as temperature increases. The inset shows the difference of spectrum. A feature at 287 nm changes over the temperature range and is attributed purely to tyrosine absorption. There is also no red-shift in the absorption maximum 278 nm. A change in the UV difference spectra of tyrosine absorption has been used to monitor protein tertiary structure of globular proteins as they denature. [17, 22, 23, 24] Fig. 5.2 shows an increase in absorption as the temperature increases. A transition temperature of 302 K is calculated from Eq. 5.5 after a fit to Eq. 5.4. Since three of the four tyrosines
Figure 5.1: *Temperature dependent absorption spectra of αSyn* The spectra of αSyn at 0 °C (blue), 100 °C (red), and the difference spectra (magenta) is also shown in the inset. Note that the peak maximum at 278 nm has not shifted with temperature.

are located in the C-terminal region, this may imply a conformational change is occurring in this region.

Future studies will require parallel melting of model compounds, L-tyrosine, to determine the overall temperature-dependence of tyrosine residues that is not associated with structure changes. Also, baseline shifts should be taken into account by simultaneously monitoring at 315 nm.

5.4.2 Circular Dichroism

CD has been used to evaluate protein secondary structure characteristics for 40 years. [25, 26] X-ray crystallography advanced the field by generating more accurate basis spectra for α-helix, random coil, β-pleated sheet and β-turn. Since the basis functions are generated from crystalized protein structures, they may not be
Figure 5.2: *Fit to the absorption evolution at 287 nm of αSyn versus temperature.* In the bottom graph, data is represented by the red circles and the fit line is in blue. The residuals are plotted in the top graph in red circles.

applicable to understand IDPs directly. Fig. 5.3 shows the change in CD spectra at low and high temperatures. The magenta difference spectrum is characteristic of a extended-β secondary structure. By first glance, the αSyn appears to be folding as the temperature increases. There is very little aggregation of the protein at high temperatures and we do not expect this to be the cause of the phenomenon. The spectra may be deceptive because CD reports on the weighted average of the gross secondary structure components based on *folded* protein conformations. Nonetheless, by monitoring evolution the 198 and 222 nm ellipticities there is a small inflection point suggesting a change in state. (Fig. 5.4) We calculate this point to be at 290 K. The transition occurs 12 degrees cooler than in the tyrosine absorbance measurement. This just may be indicative that CD is reporting on different conformational aspects of the protein.
Figure 5.3: *CD spectra at high and low temperature.* Blue squares and red circles represent CD spectra at 10 and 110 °C, respectively. The inset shows the representative spectra for a characteristic random coil, β-sheet and α-helix. The difference spectrum is plotted in magenta triangles and mimics the β-sheet spectrum.

5.4.3 Dynamic Light Scattering

DLS is used to monitor the hydrodynamic radius profile over the temperature incubation. As the temperature increases, the R_H becomes bigger ranging from about 3.08 nm at low temperature to 3.22 nm at high temperature. The increase does not have any noticeable inflection point. When fit to the two state model, the γ parameter converges to approximately 1. One could speculate that there is no cooperative transition in the R_H. However, this data set has only 13 points making a possible transition point difficult to identify. For perspective, consider that CD and UV data have hundreds of data points. Therefore, the data may not be strong enough to call this experiment non-cooperative.
Figure 5.4: *Global fit to the evolution of CD ellipticity at 198 and 222 nm at 287 nm of αSyn versus temperature.* In the bottom graph, the blue and red dots represent the data of the 198 and 222 ellipticity, respectively. The fit is represented by a solid line of the same respective color. The residuals are plotted on the top of graph.

Method	γ	ϵ	O_0	O_1	$O_{0'}$	$O_{1'}$	T_m
CD	246	13300	1.48	-3.71	-25.1	-3.41	290K
UV	96200	28900	0.126	0.189	n.a.	n.a.	302K
DLS	1.31	3290	2.34	5.30	n.a.	n.a.	No Trans.

Table 5.1: *Table of fit parameters and T_m for spectroscopic fit.* Fit parameters are described in the text. T_m is calculate from Eq. 5.5. $O_{0'}$ and $O_{1'}$ are used for the global fitting of 198 and 222 nm CD data. The observables (O) are in units of the measurement, γ is dimensionless, and ϵ is in Joules.

5.5   Discussion

The transition temperatures observed in the CD (Fig. 5.4) and UV (Fig. 5.2) data are different, yet have a common feature: the protein seems not to exhibit classic
Figure 5.5: *The evolution of hydrodynamic radius as a function temperature for αSyn.* R_H increases linearly over the temperature incubation from 3.08 to 3.22 nm.

unfolding behavior. The native to unfolded transition is typically characterized by an increase in random coil secondary structure, and a red-shift in the UV spectrum. Instead, there is no shift in the spectrum and there is an increase of ellipticity at 198 nm (in lieu of decrease at 222 nm) corresponding to gaining structure. However, DLS data (Fig. 5.5) clearly shows the protein is swelling as the temperature increases.

In chapter 4, we conducted preliminary time-resolved fluorescence (TRF) experiments using a conformationally sensitive fluorophore to probe local environments and infer conformational changes in αSyn. The advantage of TRF is twofold: fluorescence is a very sensitive technique (as compared to UV and CD which are absorption measurements), and lifetime analysis allows for elucidating local

environmental local states of the probe. Evaluating fluorescent lifetime distributions using the same statistical mechanical formalism used in this chapter is possible. Unfortunately, for the experiments that were conducted, there is not enough data (five to nine temperatures) to prepare a fit and generate a T_m.

We can still inspect the lifetime evolution for trends. The transitions are loosely consistent with those in UV and CD. In Fig. 4.5, a fast lifetime component (designated by a the left square) appears at about 293 K for Alexa conjugated αSyn. We speculated that this was due to a quenching mechanism resulting from contact with the protein at higher temperature. The temperature dependence of the NR conjugated αSyn in Fig. 4.9, shows a shift of a feature (diamonds) to a longer lifetime with a mid-point of approximately 303 K.

Though the probes are covalently attached to the protein at the same position (cysteine residue 19), they have significantly different properties. Alexa is fairly hydrophilic and may prefer to spend most of its time in the solvent. At about 293K, the protein interactions with Alexa seem to increase at approximately the same time as the increase in CD signal corresponding to an extended β-structure. Since the protein is labeled on the N-terminal portion, this suggest there is a conformational change occurring in this region. UV absorption changes occur at approximately 302 K. Three of the four tyrosines are in the C-terminal region suggesting that different parts of the protein are conformationally changing at different temperatures.

The NR is harder to explain because its hydrophobic qualities may induce some local collapse. The lifetime temperature trend is similar to 287 nm absorption but the connect between the two phenomenon is not known.

5.5.1   Future studies

We suspect that NMR studies of αSyn backbone may differentiate the structural changes on a per residue basis. Theoretically, the same statistical mechanical

formalism can be applied such that chemical shifts for each unit in the polypeptide chain (N=140) has its own parameter for the lower (O_0^n) and upper (O_1^n) pure observable, cooperativity (γ_n), and energy (ϵ_n). After each unit is fit locally, parameters can be coupled based on their similarity. Then a global model can be implemented with (hopefully) substantially less parameters. The global model may point to different regions of the protein that may go under conformational changes independently from the rest of the system, in other words, exhibit local cooperativity. Similarly, an ensemble of structures can be generated through computer simulations. By increasing the temperature, the ensemble of structures should change. With atomic coordinates available, converting to a physical observable, for example R_H or secondary structure propensity is trivial.

5.6   Conclusions

αSyn is a intrinsically disordered protein that has no known function. However, its primary sequence is highly conserved across species. Understanding the monomeric conformational properties may lead to elucidating its function. We have shown that with increasing temperature there are subtle spectroscopic transitions present in the CD and UV data. The CD signals suggest there is a secondary structural change occurring at a T_m of 290 K. Tyrosine absorption evolution suggests a transition at 302 K and may be indicative of a conformational change in the C-terminal region. The spectroscopic transitions are subtle and the connection to the macroscopic thermodynamic states are speculative. However, this type of analysis does help to formulate the hypothesis that different regions of the protein are going through conformational changes at different temperatures.

Chapter 6

Aggregation methods of α-synuclein.

6.1 Summary

Proposed aggregation mechanisms of α-synuclein fit a sigmoidal model of *in vitro* amyloid formation. This includes lag, growth and elongation phase. The phases are usually explained via nucleation mechanism. We show that differences in sample preparation and aggregation conditions change self-assembly rates and suspect that the balance of critical intermediate species are shifted. We have found that methods typically used for investigation of amyloid formation *in vitro* involve incomplete filtering and vigorous shaking. We suggest several other experiments that can be done to elucidate the intermediate species in a more controlled way.

6.2 Introduction

Mechanism and amyloid formation.

The dogma surrounding the mechanism of amyloid formation is rooted in the observations of sigmoidal fibril growth *in vitro*. 6.1 The kinetics are described in three main phases:

1. a lag phase, in which monomers conformationally convert to nuclei exhibiting the typical amyloid cross-β structure. This continues until a critical concentration of nuclei is reached, marking the beginning of the

2. growth phase. During this phase, nuclei quickly grow into protofilaments
Figure 6.1: *Classic sigmoidal kinetics of amyloid fibrils in vitro.* Left panel: The canonical explanation of amyloid growth has been proposed from histological staining assays *in vitro*. The explanation involves three phases: lag, growth and elongation. Right panel: Adding pre-formed seeds eliminates the lag phase. [27]

via monomer addition. After the monomer concentration is sufficiently depleted, the

3. elongation phase begins; fibers elongate and laterally assemble but few new fibers are formed.

This construct was determined by assaying for loss of monomer and growth of amyloid. Consistent with the model is evidence that "seeding" the aggregation with fibrils eliminates the need for a lag phase. Even so, without fundamentally violating the three phases a variety of kinetic mechanisms have been hypothesized [16, 19, 8, 13] because the intermediates, the nuclei, are never observed directly.

Parkinson's Disease is the second most prevalent late-onset neurodegenerative in the United States. [2] The disease is technically defined by the clinical symptoms, which include resting tremors and deficient initiation of motor skills. Only up to 30% of diagnosed patients meet the pathological criteria a substantial presence of neuronal Lewy bodies in the substantia nigra leading to neuron loss. This has led researchers to shift attention to pre-fibrillar aggregates in lieu of the

fibrils themselves. Understanding the nuances of the true mechanism (i.e. identifying intermediate species) may have direct relevance to the development of the effective preventative therapeutic agents. [22, 24, 7]

Incubation conditions affect aggregation rates.

α-Synuclein (αSN) is the major fibrillar component of Lewy bodies. [3, 2] Table 6.2 is a select list of publications that have investigated αSN amyloid formation properties. The preparation of monomeric protein and incubation conditions (i.e. shaking, stirring, quiescent, etc.) have the largest effect on aggregation rates. Having pure monomeric protein at the start of any incubation is critical. Remember, the canonical explanation of amyloid formation involves the notion that reseeding eliminates the lag phase. Incubation conditions are also very important since it was shown nearly 80 years ago that shaking promotes protein aggregation.[21]. Stirring with Teflon stir bars has also been shown to increase aggregation rates, even when the headspace has been eliminated. [23]

As shown in Table 6.2, starting and incubation conditions are critical factors for the rate of amyloid formation. Not only must these have to be considered during experimental design but also when considering potential mechanisms. In fact ignoring these effects may lead to a gross misunderstanding of the experimental observations.

Experimental design

In this chapter, we investigate six possible starting and three different aggregation conditions in order to (1) establish an appropriate protocol for generating αSN fibrils, (2) investigate and explain any differences in timescales of amyloid formation due to starting and aggregation conditions, and (3) design future meaningful experiments.

Native gel electrophoresis is utilized to investigate the content of the starting

material prepared for two different methods typically found in the literature of preparing the αSN. A fluorescent stain adds several orders of magnitude sensitivity as compared to visible stains in order to more easily identify aggregates. **Method 1** dissolves lyophilized αSN in an unbuffered strong base, then neutralizes with strong acid, followed by centrifuging to remove insoluble aggregates. **Method 2** reconstitutes lyophilized protein in buffer directly, passed through a 100 kDa molecular weight cutoff (MWCO) filter to remove insoluble material. **Method 3** is a variation of **Method 1** but not used for the incubation studies. This method utilizes buffered basic and acidic conditions to dissolve aggregates as a way to keep the protein from being exposed to extreme pH conditions and to potentially have increased reproducibility of the method.

The four starting/incubation conditions studied are:

1. **Method 1** (100 kDa MWCO filtering) / shaking or FS

2. **Method 3** (base dissolving, centrifuge) / shaking or US

3. **Method 3** (base dissolving, centrifuge) / rotating or UR

A fourth unfiltered, quiescent experiment is also conducted as a control. It was monitored only with light scattering because its gestation time was expected to be much longer than its agitated counterparts.

The presence of amyloid is assayed using steady-state thioflavinT luminescence (SS), static light scattering (SLS) and atomic force microscopy (AFM). ThioflavinT (ThT) gains a new excitation band at 450 nm when dimers (or more) couple in a structured environment. ThT luminescence is often used to assay for amyloid cross-β structure. Atomic force microscope images were taken to confirm the presence of amyloid fibrils at the conclusion of experiment. Though not a specific test for amyloid, SLS can be a useful tool for reporting the change of the size of scatters in solution. As the solute aggregates, the scattering intensity will increase.

Time-resolved fluorescence (TRF) and dynamic light scattering (DLS) are two methods utilized to gain more specific information about species in solution along the incubation time course. DLS has been used extensively to monitor protein aggregation [15, 17] and will be used primarily to track the early aggregation stages. ThT lifetime measurements are useful in elucidating different types of binding modes or aggregate species along the amyloid formation pathway. [5] The GIPG procedure [6] was used to fit the evolution of the lifetime and particle size distributions over the time course for the TRF and DLS, respectively.

6.3 Methods

Chemicals

ThT, aminopropyltriethoxysilane (APTES), and dibasic and monobasic sodium phosphate were purchased from Sigma.

Protein Preparation

Escherichia coli BL21 DE3 strain (Invitrogen Inc.) were transfected by plasmids (pT7-7) encoded human αSN A19C mutant and were gifts from Professor Jean Baum (Rutgers University, Piscataway, NJ). Expression and purification of mutant αSN followed published protocols. [25]

Sample preparation for time-zero Native Gel

Three primary methods were used to compare different preparation methods for αSN:

Method 1 was adopted from Ref. [18] by the best of our abilities. 1 mg of lyophilized αSN was reconsitutied in 10 μL of Millipore water with 3 μL of 0.1 N NaOH at room temperature to dissolve insoluble aggregate species. After 20 minutes, 3 μL of 0.1 N HCl was then added to lower the pH. 894 μL of 10mM

Ref	Time / days	Conc. / mg mL^{-1}	Buffer	Polishing Step	Aggregation Conditions
[18]	0.4-2.9	1.0	0-1000 mM NaCl, 10 mM NaPhos, pH 8.4	pH 10 w/ NaOH, then pH 7 w/ HCl, ultracentrifuge at 10^5 rpm for 5 min	agitated w/ plate reader and teflon ball
[11]	1	1.0	20 mM Tris-HCl,100 mM NaCl, pH 7.5	see Ref.[18]	agitated w/ stir bar
[9]	1.3	1.0	100 mM NaCl, 20 mM NaPhos, pH 7.5, 20 mM ThT	See Ref. [18]	shake at 600 rpm
[14]	2.1	1.0	20 mM Tris-HCl, pH 7.5 and 20 mM acetate, pH 3.0	Ref. [18], ultracentrifuge at 14,000 rpm for 10 min	agitated w/ stir bar
[10]	3.3	1.1	TBS	100 kDa MWCO filter	rotated 60 rpm
[26]	17	15	25 mM Tris-HCl, pH 7.5, 1 M NaCl	used directly after chromatography	quiescent
[1]	30	4.3	20 mM NaPhos, pH 7.5, 0.03% NaN$_3$	100 kDa MWCO filter	quiescent
[3]	60+	4.3	10 mM NaPhos, 2.7 mM KCl, 137 mM NaCl, pH 7.4	100 kDa MWCO filter	quiescent

Table 6.1: A select list publications concerning aggregation of αSN. Time to the beginning of the growth phase is dependent on preparation of monomer protein and agitation conditions. All incubations in this list carried out at 37 °C.

phosphate, 200 mM NaCl, pH 7.4 was added to reach a total volume of 1 mL. Th final pH was tested to be 7.15. Sample was split. One portion was spun at 16,000 rpm in an Eppendorf centrifuge at 10 °C and the supernatant was placed in Lane 8 of the Native Gel. The other portion placed in Lane 9.

Method 2 replaces the base dissolving step with reconstituting protein directly into 10 mM phosphate, 200 mM NaCl, pH 7.4 buffer then passed through a 100 kDa MWCO Microcon centrifuge filter from Millipore. The filtrate was placed in lane 3, while the retentate was placed in lane 4. Similarly, sample passed via a 30 kDa filter was placed in lane 5 and the retentate in lane 6. Unfiltered samples were placed in lanes 2 and 3.

Method 3 dissolves the lyophilized protein in a basic buffer. 6.5 mg of αSN was dissolved in 1 mM Na_3PO_4 at pH 11 for 20 minutes at room temperature. 116 μL of 0.5M phosphate buffer at pH 6.8 was utilized to bring the pH back down. After 1mL of 1.2M NaCl was added, the concentration of the protein was determined to be 1.77 mg/mL using an extinction coefficient αSN of 0.4 mg cm^2. Millipore water was added to a final concentration of 1 mg/mL. Sample was centrifuged as above and placed in Lane 7.

Sample preparation for incubation

Samples were prepared labeled UR, US, FS, for unfiltered-rotated, unfiltered-shaken, filtered-shaken, respectively. US and UR were prepared by **Method 1** using 1.2 mL of the stock 1.0 mg/mL αSN in matched type-47 semi-micro quartz cuvettes with screw cap from NSG Precision Cells Inc. (Farmingdale, NY). FS was prepared by **Method 2** and added to the cuvette. Samples were incubated in the presence ThT as in Ref. [18]. 6 μL of 1 mM ThT was added making a final concentration of 5 μM. All samples were very gently mixed prior to incubation. There was about 1.7 mL of headspace in each cuvette. UQ was prepared by reconstituting **Method 2** but was not filtered. Only SLS was measured on this sample.

A homemade shaker tray was built for these experiments and made from a Styrofoam cuvette holder attached to a FISHERbrand Vortex Genie 2 (model 2-812). The tray was oriented such that two cuvettes laid flat with the wider

inner dimension parallel to the plane of the floor. The shaking rate was measured to be about 590 rpm. For the rotated sample, the cuvette was secured on "Roto-Torque" (model 7637) wheel rotator at 47 rpm. Samples were agitated at 37 °C. Every 45 to 60 minutes, a sample was removed and measurements were taken in a quiescent condition. The total incubation (including measurement time) was nearly 20 hours long.

ThioflavinT assay

SS measurements of ThT luminescence was made using a Cary with a Peltier heating unit. Excitation was 450 nm with a 5 nm slit. Emission was observed from 462 to 650 nm at a rate of 300 nm per minute with a 5 nm slit.

TRF measurements were acquired by time-correlated single-photon counting with a setup previously described [5]. In order to monitor laser stability during a particular incubation time point, ten separate data transients were taken, each for 30 seconds. After ensuring that time-zero populations for each data trace were consistent, the data was added together. Peak intensity ranged from several hundred counts at the beginning of the incubation to over 100,000 by the timecourse completion.

ThT lifetime distributions were globally fit using GIPG [6] on a 60-point grid, logarithmically-spaced in lifetime ranging from 0.01 to 10 ns. GIPG only assumes that there is a smooth transition of fit parameters (in this case, the inverse Laplace transform of a instrument-response-convoluted exponentials) along the experimental coordinate. Over the course of 20 hours of incubation time, laser fluctuations may corrupt this continuity condition. Therefore a correction factor was applied to the overall intensity of the transients based on the SS ThT intensity measurements because they have a more reliable and consistent power source. This was done by first completing an Active-Set fit on the unperturbed data. [6, 12] The GIPG algorithm was originally set up to fit TCSPC on

a population-weighted basis, but the parameters can intensity-weighted by multiplying the amplitude of a parameter by its corresponding lifetime. A correction factor was created by comparing the sum of the intensity-weighted parameters for a particular incubation time (not considering the scattering or baseline terms) to the total sum intensity of the steady-state emission between 478 to 487 nm (corresponding to the slit width used for the lifetime measurement). A multiplicative correction factor was applied to the TCSPC data for each transient and the error was propagated accordingly. The data was fit using 200,000 iterations with a step parameter of 0.9. Probability-to-reject (as compared to the Active-Set fit) was always less than 0.05.

DLS and SLS assay

DLS experimental setup and cleaning procedure has been described previously [5], with the exception that the samples were contained in reduced volume cuvettes. Three correlation functions were obtained per sample, per incubation time for 30 seconds at 37 °C. Data was averaged and error was propagated accordingly. On occasion, correlation functions were discontinuous and were discarded. This occurred most with the unfiltered samples, especially at late incubation times. Scattering count rates (SLS) were simultaneously recorded with correlation functions.

Data was fit using the GIPG method on a 91-point, logarithmically-spaced grid containing seven decades of decay time from 0.0001 to 100 ms. The first and last decades each had five points, whereas the remaining contained twenty decay times per decade. Third derivative regularizer was implemented and all fits had a probability-to-reject of less than 0.01 as compared to an Active Set fit. 100,000 iterations and a step parameter of 0.9 were used.

Decay time was converted to hydrodynamic radius as shown in Ref. [5]. The viscosity of the buffer solution, η_0, at 37 °C was 0.7345, measured by VISCOlabs

4100 viscometer. The refractive index of the buffer was taken to be 1.334. The characteristic density of the αSN determined from assignment of a temperature titration DLS experiment in chapter 5 was used to scale the oligomer sizes by $R_{H,monomer}N^{1/3}$, where N is monomers per aggregate.

AFM

Preparation and execution of AFM measurements have been previously described in Ref. [5]. AFM was taken at the conclusion of the experiment.

Native gel electrophoresis

A precasted Novex Tris Glycine Native gel was run via the Invitrogen protocol. NativeMark Unstained Protein Standard was used as the marker. The gel was stained with the fluorescent SYPRO Ruby Protein Stain (BIORAD).

Photograph of final product

A photograph was taken at the completion of the incubation with a Samsung Flipshot (SCH-U900) cellular phone.

6.4   Results

6.4.1   Initial conditions

Native gel electrophoresis reveals the differences in preparation procedures. 6.2 The monomer band sits just below the 146 kDa molecular weight marker. In contrast to the standards, αSN is not a globular protein. In fact the hydrodynamic radius of αSN is more similar to the characteristic radius of human insulin protein, molecular weight of 65 kDa. Filtering with a 100 kDa filter may remove particles as small as αSN dimers and certainly tetramers.
Figure 6.2: *Fluorescently-stained native gel electrophoresis of selected preparations of αSN.* Lanes are fully explained in the text. Specifically, lanes 2-10 (UQ), 3 (FS) and 8 (UR and US) represent the three starting conditions used for incubation in this chapter. The 100 kDa filtering method is the only effective way to remove pre-formed aggregates. (lane 3).

The control samples, lanes 2 and 10, were dissolved directly into buffer and contained a significant population of higher molecular weight species. Protein prepared by methods 1 and 2, in lanes 7, 8 and 9, were dissolved at high pH. Method 2 was designed around the notion that protein should always be under buffering conditions. A side benefit may be increased reproducibility as compared to method 1. Unfortunately, neither of these methods remove higher order aggregates as compared to the control even when centrifuged for 20 minutes (as in lane 8). Lane 3 (method 3) shows no presence of aggregates, presumably because

100 kDa filter removed them. It is apparent from the 100 kDa retentate in lane 4 that aggregates are present in the unfiltered samples. As a final test, a 30 kDa filter was implemented in lanes 5 and 6, but the results were puzzling. Lane 5 is the filtered solution but looks similar to the unfiltered control, but less intense. Though the retentate in lane 6 has aggregate species, there is a significant monomer contribution.

6.4.2 Final product - Visual Inspection and AFM

Visually inspecting the samples at the completion of the experiment is a reality check for the spectroscopic measurements and is shown in Fig. 6.4. All samples exhibited bubbles filling the headspace. Both FS and US have a similar bubble size and density as compared to UR. Crudely estimating, there are 3 larger bubbles and 5 smaller bubbles that stretch across the 1 cm width of the cuvette for UR and US, respectively.

US had a yellow "milky" color with fine suspended particulates. UR had a yellow tint, but also had large particulates that were prone to settle to the bottom of the cuvette. Conversely, the FS sample was clear and had a slight yellow hue similar to that of a stock 5μM stock solution of ThT.

AFM images in Fig. 6.3 were taken to ensure amyloid fibrils were being generated. The results were consistent with the visual inspection of the sample after the conclusion of the experiment. Several AFM images of the FS sample were taken; fibrils were a rare find. This may be expected since the sigmoidal pattern of static light scattering and ThT luminescence was not observed for this sample. Furthermore, the sample was still clear to the eye by the time the AFM sample was prepared.

On the other hand, US was hazy visually and the corresponding AFM image exhibited a fairly dense fibril network across the entire modified mica surface. This suggests that if fibril species do exist they will adhere to the surface. Proper
Figure 6.3: *AFM images of the UR, US and FS samples.* Images only show the presence of fibrils in US. However, we suspect that particulates are too large in UR to stick to the modified mica surface. FS shows no signs of aggregation in any assay and therefore the resulting image is expected.

AFM images of UR, however, showed an occasional round particle with nothing much else sticking to the surface. Recall that this sample had large, chunky particulates that sank to the cuvette bottom. This suggests that particles were massive that could not survive the rinsing step necessary to take an image.

6.4.3   SS ThT Assay

Using the ThT luminescence the canonical expectation of the sigmoidal character is shown in Fig.6.5. All three samples have a similar lag phase in the first 3 hours of incubation. US and UR have a large increase in ThT signal at approximately hour 10. This is indicative of a growth phase of protofibrils. US begins to plateau after about 16 hours, marking the beginning of the elongation phase. During this phase, fibrils extend while few new fibrils are formed. UR reaches this plateau over an hour later (hour 17). After hour 10, there is a slow increase in luminescence for FS. However, relative to US and UR, FS appears not to have reached the dramatic growth phase. Based only on this data set, it is difficult to determine if this sample would *ever* reach a growth phase.
Figure 6.4: *Photograph of the final condition of αSN agitation experiment in the presence of ThT.* The UR, US and FS samples are labeled. The image shows that agitation was rigorous enough to create bubbles to fill the headspace. FS is clear and does not show any visible signs of aggregation. US has very finely suspended particulates, whereas UR has large precipitate with some settling at the base.

Preparation and condition had a profound affect on the aggregation profile of αSN. This is compounded by the fact that the lag phase appears to be bifurcated into early and late lag sub-phases. This trend is the most obvious in US. After hour 3, US increases slightly suggesting that a species is being generated that has the ability to bind ThT in a specific way. There is an increase in FS and UR at this time, but not as dramatic.

Above we drew attention to specific incubation time points where there existed a consistent change in ThT luminescence across the samples. We have drawn three lines of demarcation defining four stages of signal change at hours 3, 10 and 16. For the remaining sections of this chapter, we will refer to stages I through IV, instead of phases, when comparing samples. Stage is only a phenomenological
Figure 6.5: *steady-state ThT luminescence assay for amyloid fibrils.* The trend of fibril formation differs with each sample. Vertical purple, brown, and magenta dashed lines demarcate four stages (full explanation in the text).

construct to help organize congruent timescales in order to avoid using the term "phase" since mechanistic explanation of the data is then implied.

6.4.4   SLS

The average scattering intensity along the incubation time course is plotted in Fig. 6.6. SLS is very sensitive to aggregation trends of a sample during the early stages of the incubation. The disadvantage is the lack of specificity for protein conformation. Regardless, the expected classic sigmoidal growth pattern is observed for unfiltered samples within the 20 hour time window.

During stage I, both UR and US have an immediate intensity increase. There is no increase for FS. FS remains at essentially the same count rate well into stage III. UR, on the other hand, continues to slowly and smoothly increases during stage II . US increases by two-and-a-half times from the beginning to end of stage II. This is the same stage which produced ThT luminescence for US. During stage III, the count rates for UR and US are both growing fast, while FS is just
Figure 6.6: *Static light scattering assay.* Average count rates were recorded to monitor generic protein aggregation. The classic sigmoidal curves show the typical lag and growth phases of amyloid formation.

beginning to gain signal at approximately 14 hours. US plateaus at 15 hours, but UR continues to grow as bigger particles are generated. UR reaches its plateau at the end of stage IV, as FS records a big change in scattering intensity. It is possible to retrieve a unimodal particles size distributions from SLS data. Protein aggregate distributions are expected to be multimodal with sub-populations of evolving over time. Fitting SLS data loses applicability in this case, and DLS is utilized instead.

A single sample of completely unfiltered αSN was examined to determine the timescale of aggregation without agitation of any kind. In Fig. 6.7, SLS of a quiescent sample was monitored over 90 hours. Even though this sample was reconstituted directly in buffer, with no filtering step, the quiescent sample did not begin to aggregate until 75 hours after the start of the incubation.
Figure 6.7: *Static light scattering assay of UQ.* Average count rates were recorded to monitor generic protein aggregation. Note that the lag phase is about seven times longer for a quiescent sample.

6.4.5 Dynamic Light Scattering

GIPG analysis of DLS was used to elucidate particles size evolutions across incubation time (see Fig. 6.8). The fit parameters are converted to spherical particles sizes represented by the hydrodynamic radius, R_H . Spherical shape may be a decent approximation for monomeric and oligomeric species (3.3 to 10 nm). Under conditions where amyloid formation is not expected, spherical medium to large protein aggregates (10 to 200 nm) is also a valid assumption. However, under the current setup, there is no way to know if these aggregates are globular or rod-like. This represents the first caveat. A second caveat concerns the inability to detect small particles in the presence of large ones. DLS is only useful at early times when most particulate matter is less than half the wavelength of the incident light (or about 215 nm in this experiment). The reduced data is displayed out to 400 nm only to give a sense of the size of super-aggregates (< 200 nm) along the
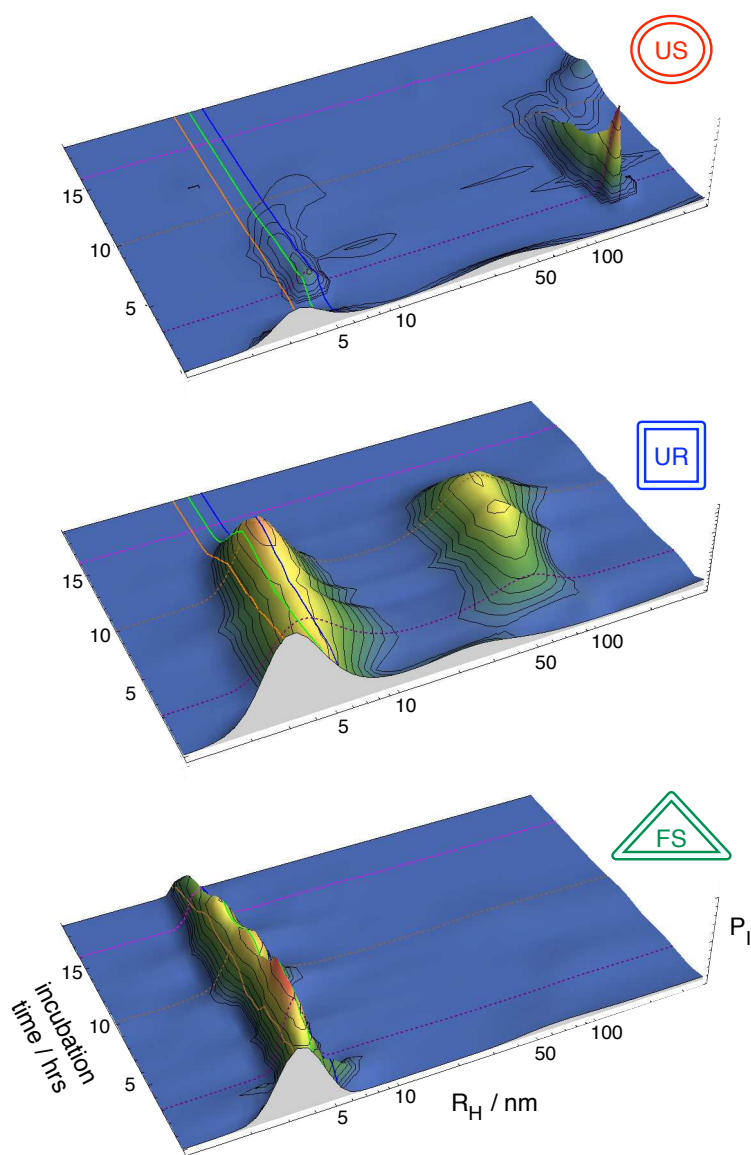

Figure 6.8: *The fit parameters of the DLS data using GIPG.* US, UR and FS are labeled from top to bottom. Orange, green and blue mesh lines correspond to the predicted hydrodynamic radius of a spherical monomer, dimer and tetramer, respectively.

evolution.

At time zero all samples have a monomeric peak with an approximate R_H of 3.4 nm. However, there are significant initial medium-sized aggregates for both UR and US. Orange, green and blue lines represent monomer, dimer and tetrameric

species by scaling the monomer unit by constant density. Even though UR and US were prepared in identical fashion, US has slightly larger and greater concentration of initial aggregates. FS does not have any aggregates. The time-zero aggregates were consistent with native gel.

As stage I progresses, there is immediate oligomerization in all samples. UR has a wide particle size distribution for the oligomeric species with a mean about the same as a tetramer. Also, the initial medium-sized aggregates have grown to large (70 nm) species. This distribution is wide suggesting a range of particles sizes. DLS data was corrupted during hours 1 and 2 for US and were not used in the analysis. We cannot comment on the evolution during this stage. There are no aggregates formed in FS as measured by DLS. In this sample, the monomer oligomerized to form a narrow distribution of dimeric species.

At the start of stage II, fairly monodisperse, large (180 nm) aggregates dominate the intensity signal in the US. US also self-associates monomers into narrow distribution of sizes consistent with a trimer. This peak slowly decreases and shifts to large oligomers by the conclusion of stage II. In terms of large aggregates, in the US sample there is steady decrease, whereas UR slowly gain population. FS does not have any detectable aggregates present. Keep in mind, the parameters represented in Fig. 6.8 are intensity-weighted and do not reflect number of particles in solution. Converting intensity-weighted parameters to number-weighted parameters reveal that the large aggregates are seven to eight orders of magnitude less in number than the time-zero monomer population. This would be consistent with the notion that metastable species present in the amyloid formation mechanism are short lived (or low population).

For UR and US, stage III represents the approximate time of the growth phase where there are significant increases in scattering and ThT luminescence. By the start of stage III, there are super-aggregates (approximately 300 nm) being generated in US. The disappearance of the oligomeric and large aggregates may

be due to the presence of super-aggregates swamping the signal and not due to the complete conversion of these species. Similarly, oligomeric and aggregate species in the UR sample are overwhelmed by super-aggregates after hour 12.

FS does not change much until the end of stage III. At this point, there is a slow decrease in signal coinciding with an increase in static light scattering (see Fig. 6.6). Without any evidence of intermediate aggregate particles present by DLS, the aggregation is most likely due to super-aggregates.

6.4.6   Time-Resolved ThT luminescence

The time-resolved fluorescence resolves details concerning binding environments of the intercalated fluorophore. ThT lifetimes evolve across the incubation time-course as species begin to bind ThT in a luminescence-competent way. At the beginning of the incubation little binding of ThT is observed.

The final incubation time is useful to characterize first because there is presumably fibril-bound ThT. At the conclusion of the UR and US incubation, a plateau of ThT luminescence is reached (see Fig. 6.5). 95.6% of the final intensity-weighted lifetime distribution of UR is represented by a 2.0-ns species. Most of the remaining intensity is from a shorter 660-ps species (3.6%) and longer 5.0-ns (0.58%) species. The US sample has the same 2.0-ns species but has slightly less of the majority at 93.6%. Conversely, there is small increase in the intensity of the 640 ps component to 5.7%. Also, there is a small contribution (0.28%) of a 170 ps component which is not present in the UR sample. The longest lifetime component is shifted to about 6.3 ns and represents 0.20% of the intensity. In contrast, FS has not reached a plateau in SLS or SSF by 19 hours. This is reflected by a different lifetime distribution, centered at 1.6 ns (93.0%) and 660 ps (5.9%).

At the beginning of stage III, US exhibits a 1.4-ns feature. This feature shifts slowly to 1.6 ns by the middle of this stage, as shorter 660 ps feature appears.
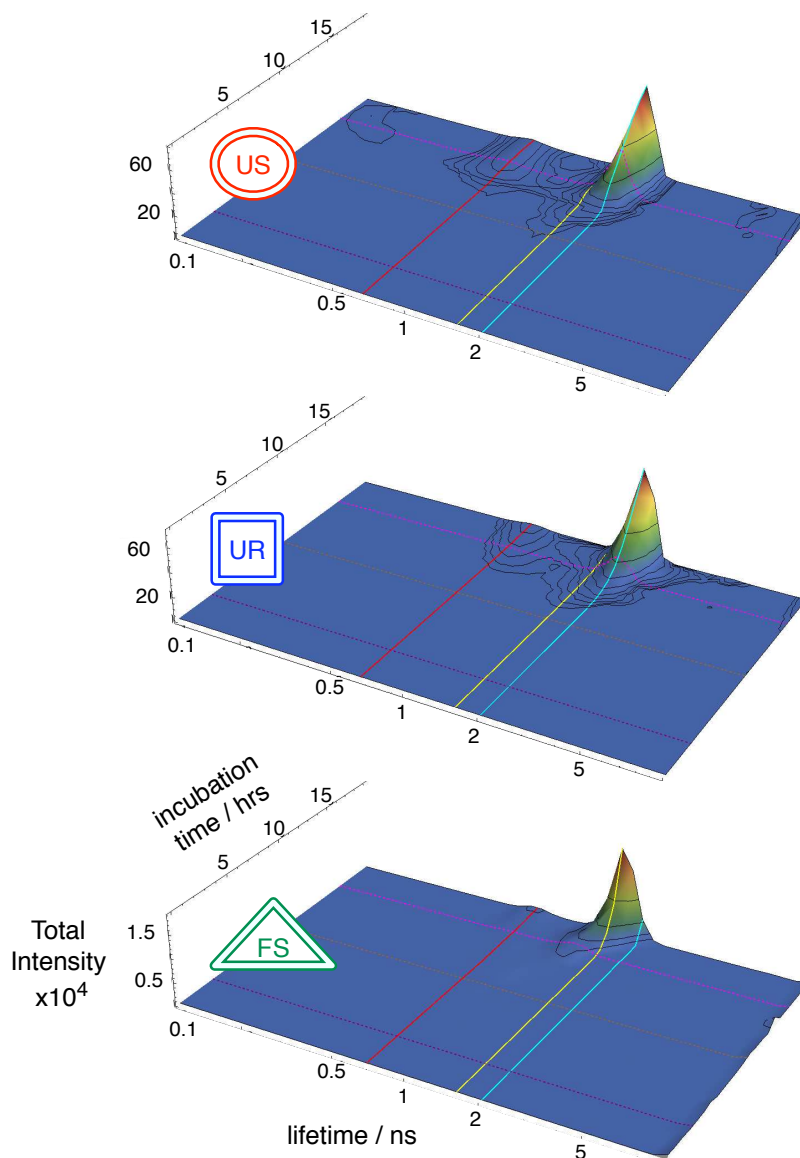

Figure 6.9: *Lifetime analysis of TRF data using GIPG.* US, UR and FS are labeled from top to bottom. Red, yellow and cyan mesh lines correspond 660 ps, 1.6 ns and 2.0 ns, respectively. We attribute the 2.0 ns lifetime feature to amyloid fibril binding, and the 1.6 ns lifetime with protofibril formation. We speculate that the 660 ps feature represents ThT bound to amyloid fibrils but an alternative binding or quenched state.

As stage III ends, most of luminescence results from a 2.0 ns component. The increasing trend of this species plateaus during stage IV. UR has a similar lifetime trend as US. Both have an increase growth of a 1.6-ns species which shifts to 2.0 ns

later in the stage. However, UR does not have a 1.4-ns feature.

The small ThT SS intensity present at the end of stage III in FS (see Fig. 6.5) is due to a short 1.2-ns lifetime. The lifetime shifts during stage IV to 1.6 ns. This lifetime has preceded the growth of a 2.0-ns species that was present at the end of the growth phase in UR and US. The added lifetime information suggests that FS is on pathway to form amyloid fibrils.

6.4.7 Data recapitulation

FS

Filtering reconstituted αSN with a 100 kDa MWCO filter left only monomeric species shown by native gel (Fig. 6.2) and time-zero DLS (Fig. 6.8). Particle size distribution evolution measured by DLS showed an initial dimerization within stage I, but no significant increase in SLS signal was reported (Fig. 6.6). In fact a significant scattering trend did not occur until the middle of stage III. However, ThT luminescence (Fig. 6.5) increased from stage II through stage IV, without the sharp growth phase as shown by UR and US. The majority lifetime responsible for this increase starts at approximately 1.2 ns and shifts to 1.6 ns. The 1.6 ns feature was shown by both UR and US during the stage III, or the growth phase. AFM images (Fig. 6.3) do not show any fibril structures attached to the modified mica surface and, upon visual examination (Fig. 6.4), the sample was clear without particulates present.

US

Native gel and time-zero DLS showed presence of aggregate species at the start of the experiment. During the stage I, a narrow distribution of oligomeric species were created from self-associating monomers. At the end of stage I, there was a significant increase in scattering signal as shown by SLS. Interpretation of DLS

suggests that the increase of SLS signal was most likely due to large, narrowly distributed particles converted from the presence of time-zero aggregates.

No ThT signal was demonstrated until the beginning of stage II. During stage II there was a modest ThT and SLS increase, while presence of large aggregates disappeared, suggesting a conversion to super-aggregates. ThT and SLS signal increased at a greater rate at the beginning of stage III and was attributed to a growth phase. ThT lifetime distributions shifted from 1.4 to 1.6 ns, then to 2.0 ns by the conclusion of stage III. This may suggest the conversion of protofibril to amyloid fibril structures. Alternative binding orientations may be responsible for shorter lifetime components of approximately 650 ns.

By stage IV the SLS and ThT intensity plateaued as shown in Fig. 6.5. The intensity trend is indicative of a slower rate to the creation of new aggregates; the 2.0 ns lifetime implies the aggregates are amyloid fibrils. The argument is strengthened by AFM imaging (Fig. 6.3). Amyloid fibrils stuck to the surface and demonstrated a network of fibrillar structures and was consistent with the final solution of small suspended particulates. (Fig. 6.4).

UR

As in US, native gel and time-zero DLS showed presence of aggregate species at the start of the experiment. During the stage I, self-associating monomers created a large distribution of oligomeric species. At the same time, a wide distribution of aggregates were converted from the initial aggregate left after reconstitution. At the end of stage I, there was a slight increase in scattering signal as shown by SLS in Fig. 6.6. Interpretation of DLS suggests that contrary to shaking, rotating does not create a significant population of super-aggregates early on.

Little ThT or SLS signal was demonstrated until the end of stage II at which there was a dramatic change. ThT and SLS signal increased at a greater rate at the beginning of stage III and was attributed to a growth phase. ThT lifetime

distributions shifted from 1.6 to 2.0 ns by the conclusion of this stage. The 1.4-ns feature was not present in UR.

By the end of stage IV, the SLS and ThT intensity plateaued. As in US, the 2.0 ns lifetime suggests the aggregates are amyloid fibrils. US generated a thick precipitate that was not well suspended, rendering it a difficult sample for AFM imaging.

6.5 Discussion

Differences in methods

There are several recurring methodological differences present in the literature regarding amyloid incubations. These methods result in kinetics that are only marginally similar. Timescales of aggregation are often very different from investigator to investigator. We have challenged two such methods. If these differences affect the rates of aggregation, they should be included in any mechanistic explanation thereof.

6.5.1 Preparation Effects

Lyophilization is a common way to store protein in a stable environment for months at a time. Unfortunately, the drying process can create significant precipitate upon reconstitution in buffer (see Fig. 6.2) The lag phase has been shown to be eliminated by the addition of nuclei, or "seeds", to an incubating protein sample. One method to dissolve particulates has been to invoke a high pH treatment. Fluorescently-stained native gel and DLS show that even this method did not remove the smaller soluble aggregates completely. Whether using a controlled system of buffers, or strong bases/acids to monomerize protein, both are equally deficient by native gel. More importantly, the presence of these aggregates affect the overall rate of the amyloid formation mechanism.

The initial soluble aggregates may not be seeds per se. Seeds are most often thought to have the amyloid cross-β structure and act as template for monomer addition. We have not seen evidence that lyophilizing protein generates amyloid fibrils in a single step. ThT luminescence does not support the notion that the seeds present in unfiltered samples have this highly-ordered conformation.

There are subtle similarities in ThT luminescence signal between FS and US. Crudely, the aggregation of FS is one stage behind US (see Fig. 6.5). Shown in Fig. 6.9, stage II in US and stage III in FS both have short lifetime species dominating the signal. The lifetime distributions at the interface of stages II and III for US match those at III and IV for FS. Finally, the 1.6-ns species present at the end of stage IV is found in the middle of the growth phase of US. Unfortunately, without knowing the binding constants or quantum yields of different ThT intercalation orientations, converting the intensity of an intermediate feature to a population of species can only be speculated.

Initial soluble aggregates are present in the unfiltered samples and do not have the cross-β structure. Because they still facilitate aggregation, the argument of a colloidal aggregation mechanism is strengthened. However, it is presumptuous to formulate a mechanism of aggregation without considering that agitation technique also affects the intermediate species present as shown by UR and US data.

6.5.2 Agitation Effects

As shown in Fig. 6.7, quiescent samples will aggregate much slower than when agitated. In this particular case the sample was neither filtered nor prepared through a base dissolving treatment. This suggests that driving forces for aggregation are provided largely by agitation. We have not seen any literature that casts an amyloid mechanism while considering agitation effects. However, general protein coagulation by surface interactions has been discussed.

A paper published by Ascherson (cited within Ref. [21]) nearly 170 years ago, described protein solutions forming elastic "skins" in a spontaneous fashion around oil droplets. One hundred ten years later, Cumper and Alexander [4], performed a comprehensive study to measure the elasticity and surface viscosity of protein solutions at the air-water and oil-water interface under different ionic strengths, pHs and temperatures. They found a surface denaturation phenomenon in thin films, and proposed a general mechanism:

1. globular proteins diffuse to the surface, then

2. "unroll" on the surface by denaturing, and finally

3. the concentration of denatured protein packs at the surface, allowing for coagulation.

After diffusion takes a protein near the surface, a small amount of energy is needed to adsorbed it. Surface denaturation follows when hydrophiliic side chains partition into the solution and hydrophobic search for the surface. Depending on buffer conditions, the surface can become saturated with polypeptide chains that stretch across the interface. Lateral association becomes energetically favorable via protein-protein hydrogen bonds and salt bridges. [4]

We speculate that when a thin film forms and is left undisturbed, it stays in a metastable state. Changing over the surface, for example by shaking, nudges the protein out of the metastable state. When the film enters the bulk solution again, it can bud, forming an aggregate. The aggregate would still have some of the residual structure that formed at the surface. αSN is an intrinsically disordered protein (IDP) and there is no propensity to gain secondary structure in solution. To break the aggregate, a driving force, perhaps the entropy penalty by gaining structure, would have to overcome the energy holding the aggregate together. Of course there is an entropic gain by the water when creating a single larger particle.

The authors also invoke the example that egg albumin cannot be heat aggregated (Ref. [4] and references within). However, native *and* heat denatured egg albumin will self-associate when shaken. If the aggregation process is entropically driven, i.e. many different states exist but only a few are aggregate-prone, raising the temperature does not help. Raising the temperature will only work if there is an enthalpic barrier that needs to be crossed to aggregate. The driving forces behind shaking are two-fold: forces to denature (enthalpic) and organize (entropic). In the case of αSN, elucidating the thermodynamic properties of the monomer has been discussed in chapter 4.

6.5.3 Mechanistic consequences

Filtered quiescent samples take several weeks or longer to aggregate [3, 1], whereas a quiescent but unfiltered sample (UQ) showed signs of aggregation in just after three days. It is apparent that removing the initial soluble aggregates changes the kinetic mechanism by increasing the concentration of the available unstructured or colloidal aggregates. These loosely held aggregates do not show a ThT luminescence response and, therefore, does not have latent cross-β structure. In Chap. 3, we describe the first step of the self-assembly of partially denatured β-lactoglobulin A (β-LG$_A$) in terms of "Aggregate A" (aggA). αSN is an IDP but can utilize aggregation as a way to stabilize a hydrophobic core. The partitioning of hydrophobic side chains into a central core is one of the driving forces for globular proteins to fold. [20] Here, we suggest that the core of the unfiltered particulates can conformationally rearrange without losing critical hydrophobic contacts. The consequence is that the lag phase is shortened.

Shaking versus rotating

By rotating we observe fewer, but bigger, bubbles in the headspace. We consider rotating to be a more gentle method of turning over of surface proteins to the

bulk, evident by the large chunky particulates at the experiment's conclusion. We estimate at any given time during the shaking process, there is more than 40 cm^2 of bubble surface in the 1.6 mL of headspace. Rotated sample is closer to 28 cm^2.

Recall, aggA is expected to be malleable by definition. Consider that they may remain intact but breach at the surface; conditions may better align hydrophobic core on the surface before it returns back to the bulk. The steady-state ThT luminescence increases slowly during this stage for both US and FS just prior to the growth phase. This would insinuate that this process expedites the formation of "Aggregate B" (aggB). In Chap. 3, we describe aggB as a metastable colloidal assembly of proteins that has cross-β like structure. We can only speculate that these species exist based on the evidence that the typical lifetime present prior to the growth phase is shorter than that of protofibrils (>1.6 ns).

There is little evidence of a high concentration of the aggB component in UR. However, both UR and US form amyloid. Is aggB just *a* way to get to a protofibril, but not *the* way? Searching for these intermediate species by rotating versus shaking would require a host of rigorous control experiments, in order to determine how the physics of these two methods affect aggregation rates.

6.5.4   Biological relevance of *in vitro* agitation studies

What can we learn from *in vitro* experiments probing amyloid formation mechanisms that is still applicable *in situ*? Do the possible protein interactions with hydrophobic biological matter, such as *in between* a cell membrane, justify agitating protein samples to facilitate self-assembly? We speculate the answer is, maybe. Agitation and filtering methods vary from investigator to investigator, and the results reflect this.

Why, as a community, are we investigating mechanism with inconsistent experimentation, obtaining different results, and claiming that it is all the same? We believe that this question precludes both the former. The dogma surrounding

amyloid formation *in vitro* is very strong, and yet so vague that even if the results are inconsistent within the field but do not contradict the dogma, the results are considered without question. The consequence is, of course, that nothing new is learned. This and future work will hopefully convince the field that inconstancies are unacceptable, and persuade the field that the development of consistent methodologies and experiments are critical tools needed by the community to solve this outstanding problem.

6.5.5 Future experiments

Teflon beads - No head space - Rotated

It is difficult to investigate the influence of the hydrophobic air-water interface present in all samples with head space in a controlled way. Instead, we will co-incubate αSN with hydrophobic surface of Teflon beads. Without headspace, samples will be subjected to constant rotating in the presence of beads. ThT, SLS and DLS assays will be conducted. We expect that by increasing the number of beads, the aggregation rates will increase. Given that the surface area of the bead is known, the driving forces due to hydrophobic interactions with the bead can be quantitatively discussed.

Quiescent- No head space - Filtered

The amyloid formation will have to be confirmed for a non-agitated, seed-free sample without the air-surface interface. This control experiment will have to preclude any investigations involving these conditions. It is expected that this experiment will take months to complete because these three factors seem to be the biggest contributors to fast aggregation. Essentially, two practical questions can be answered at the expense of relatively simple biophysical techniques:

1. How long to incubate?

2. What time points should we pay the most attention to?

Elucidating intermediate species with TRF studies covalently-labeled αSN.

One part of understanding kinetic mechanism means identifying all relevant species. The other is to monitor the concentrations changes with time. As shown in chapter 4, there is promise for conformationally sensitive fluorophores to be used as a tool to identify species along the amyloid pathway.

The first experiment will involve a co-incubation of Alexa Fluor 488 conjugated αSN (Alexa-αSN) with native αSN. We see a lifetime distribution of Alexa-αSN change as the temperature increases beyond $37\,^{\circ}$C. We believe the probe become quenched by coming in contact with amino acid side chains. If the effect is duplicated by aggregation, there may be an independent measure of conformation that is not ThT dependent.

There are two unwanted effects that should be avoided for this experiment. First, fluorescence resonance energy transfer (FRET) between two nearby Alexa-αSN in the same aggregate may change the lifetime distribution in a complex way. Second, the properties of the probe itself may change the aggregation rate. By using 20:80 mixture of Alexa-αSN to αSN, a good balance between the number of conjugates and the number of monomers aggregate can be obtained. For example, invoking the binomial distribution a dimer has a 32% probability of having one Alexa-αSN and only 4% having two.

FRET study of the co-incubation of two different αSN conjugates

If the TRF studies of Alexa-αSN show no change in the lifetime across the incubation but still aggregates to form fibrils, a second experiment utilizing FRET can be formulated. We have found that the lifetime distribution of Atto 590 αSN conjugates (Atto-αSN) does not change much with temperature and therefore

can be considered as a good FRET acceptor for Alexa-αSN. The Förster radius for this pair is 6.0 nm, or slightly larger than hydrodynamic radius of the dimer αSN (see Chap. 6 for explanation). The experiment begins with two sets of samples. Set A has co-incubated αSN with Alexa-αSN, and set B has co-incubated αSN with Atto-αSN. At different time points along the incubation, a sample from set A is mixed with sample from set B and the FRET signal is monitored over the remaining incubation. If no FRET signal is measured, each sample has already aggregated into a stable pre-fibrillar particle. Otherwise, there should be exchange of conjugates and FRET will be detected. The fluorescence signals seen only from these species should be directly related to the creation the colloidal intermediates formed prior to the growth phase.

6.6 Conclusions

The mechanism of amyloid formation is not well understood. In the case of αSN in vitro aggregation, we have brought to light the major discrepancies in published aggregation rates. We have connected the differences to preparation and incubation conditions. We need to be careful that when describing the mechanism of amyloid formation in terms of driving forces, these experimental considerations are taken into account. We have shown in our experiments that there are unmistakeable kinetic differences between filtered or unfiltered samples, and agitated or quiescent incubation conditions. Because these effects cannot be ignored, we have proposed other experiments that have potential to identify intermediate species in a controlled way.

Chapter 7

Supplementary Materials

7.1 Summary

As with any dissertation, not every scrupulous detail can be included into any one particular chapter. Nevertheless, some "details" are quite important especially if they provide a baseline understanding of an experiment, ultimately facilitating the proper interpretation of data. This chapter consist of four figures and a short section of IGOR computer code. Explanations for each figure are given in their own section and figure caption.

7.2 Simulating DLS data

In chapter 2, we introduced a new approach to global data fitting based on a regularization condition that invoked continuity in the global data coordinate. Dynamic light scattering (DLS) was used as the original experiment for the pedagogical example (as opposed to time-correlated single-photon counting, TCSPC). DLS is used to measure particle size distributions. By numerically solving a set of differential equations developed to describe the fibrillogenesis of amyloid β-peptide [1], we set out to simulate particle size distribution evolutions along an incubation timecourse. A considerable amount of intellectual effort was put forth to ensure the proper conversion from particle size distributions to the simulated DLS data and is explained below. Unfortunately, we found that the process for
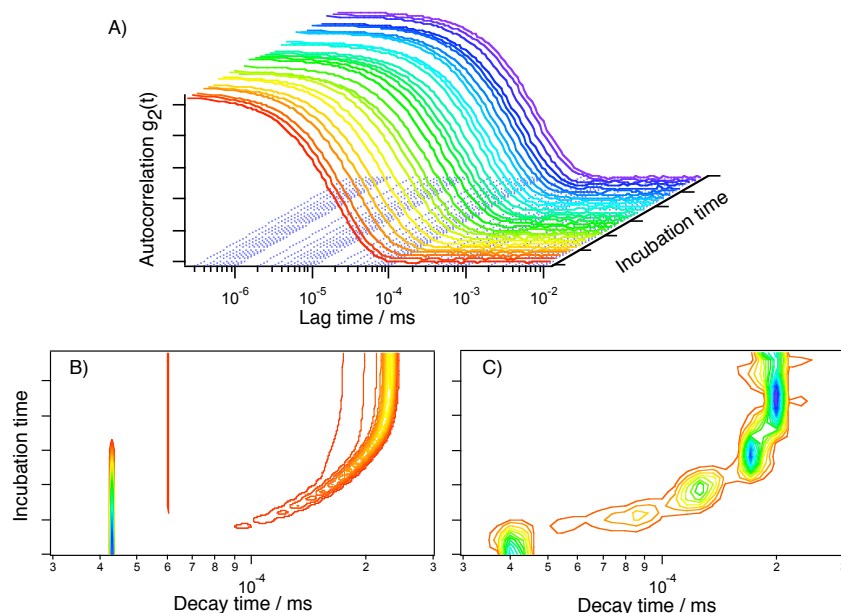

Figure 7.1: *Simulated DLS correlation functions.* **A)** DLS correlation functions representing a particle size evolution $g_2(t)$. **B)** The exemplar decay time distribution evolution used to generate the correlation functions in panel A. **C)** Fit parameters determined from a GIPG analysis to the $g_2(t)$. It took about one week to generate the DLS data for this particle size evolution. GIPG underperformed under example. However, we found that other fitting methods, such as local regularization, maximum entropy, active-set, etc., also underperformed with less accuracy than GIPG. Parameters used to simulate the correlation functions: 2^{19} points in the correlation function,125 ns was the bin width, 50 ms was the largest correlation time and 50 correlation functions per transient in order to generate the standard deviations for the data.

generating correlation functions was *very* time-consuming. Also, we were not convinced that a micelle mediated kinetic model proposed in Ref. [1] was realistic. We ultimately abandoned the kinetic model and DLS data generation for the work that was eventually completed in chapter 2 (and Ref. [2]).

When generating DLS data, the key is to see that the fluctuations of the intensity at the detector are equal to the square of the electric field phase components of each of the diffusing species. The fluctuations exponentially decay, $e^{-\Gamma_i t}$, where Γ_i is the characteristic decay rate for a diffusing particle, i. The variance of the electric-field depends on the number of particles as well as the scattering cross-section. The relative amounts of scattering for different sized particles can

be estimated by a Gaussian random variable with a mean of zero and a standard deviation equal to the square root of the characteristic scattering intensity for that size (and shape) particle. We then impose the correlation that each species exhibits onto the electric-field trajectory. Adding the resulting electric-fields yields the net electric-field trajectory. The electric-field squared gives intensity trajectory. To make intensity trajectory realistic, shot noise is added. Autocorrelating the resulting trajectory yields the intensity correlation function often referred to as $g_2(t)$. This data now has noise due to both the electric-field and intensity components. Replicate transients can be generated in order to calculate the standard deviation of the data.

Fig. 7.1 shows the evolution of generated correlation functions when the peptide concentration is at the critical micelle concentration. The particle evolution was generated by numerically solving the differential equations in Ref. [1]. The particle size is related to a diffusion constant via the Stokes-Einstein equation. The decay time evolution is then related to the diffusion through scattering vector, $D_i = \Gamma_i/\mathbf{q}^2$ (see chapter 3). The intensity of each scattering particle was estimated by:

$$I_i = CA^3 N_a \left(\frac{2\pi M_w i \, (dn/dc)}{N_a \lambda^2 D} \right)^2 I_o \qquad (7.1)$$

where C is the concentration, A is the area of the detector, M_w is the average molecular weight of particle, (dn/dc) is the index of refraction change, N_a is Avogadro's Number, λ is the wavelength of the incident light, D is the distance to the detector and I_o is the incident light power. The total intensity of all the particles for each transient was scaled to 300 kHz.

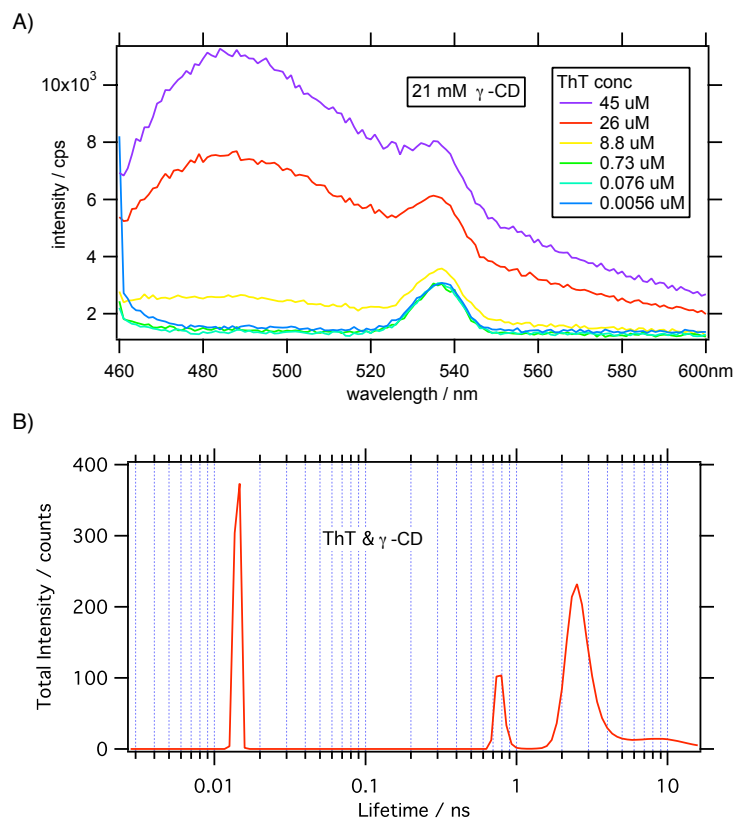

Figure 7.2: *Spectral properties of γ-CD bound ThT.* γ-cyclodextrin (γ-CD) has been shown to bind ThT and exhibit dimer luminescence signal. **A)** Steady-state luminescence spectra of ThT titrated into 21 mM γ-CD. Excitation wavelength was set at 450 nm. Slits were set to 5 nm. As the concentration of ThT increases, a 482 nm emission band grows. Note: it may take an hour or more for the complete intercalation of ThT into γ-CD. This data was taken after three days of incubation. **B)** The lifetime distribution of the time-resolved luminescence ThT / γ-CD. ThT to γ-CD concentration ratio was 26 μM to 21 mM. Locally regularized IPG was used as the fitting algorithm with a $\chi_r^2 = 1.05$. Data is displayed as total integrated intensity. Note that there are three components: 15-ps, 790-ps and 2.5-ns species. The 15-ps feature is due to free ThT. The 790-ps and 2.5-ns features were also exhibited in the presence of protofibrils and mature amyloid fibrils, respectively (see Fig. 3.5). (Fitting parameters: 50,000 iterations, 0.9 step, quadratic continuity condition, 131-point logarithmically-spaced lifetime grid from 1 ps to 21.5 ns, probability-to-reject as compared to active set < 0.01).

7.3   γ-cyclodextrin (γ-CD)

In chapter 3, we assayed for the presence of amyloid using Thioflavin T (ThT) luminescence. When bound to amyloid, ThT exhibits a new absorption band
Figure 7.3: *GIPG fit parameters for the urea titration of β-LGA in the presence of ANS.* β-LGA was placed into different concentrations of urea, allowed to sit for 15 minutes before ANS was added. TCSPC was used to measure the ANS fluorescence lifetime of the resulting solution. The data was fit with GIPG with a $\chi_r^2 = 1.03$ By following the evolution of lifetimes it was possible to assign certain lifetime features to ANS binding environments. Long lifetime features were attributed to ANS sequestering in the calyx. Note that at 5 M urea there is a loss / shift of the long lifetime features suggesting a major calyx change. (Fitting parameters: 1.75×10^6 iterations, 0.9 step, linear continuity condition, 68-point logarithmically-spaced lifetime grid from 10 ps to 33.5 ns, probability-to-reject as compared to active set < 0.01).

at 450 nm that has been attributed to ThT binding to the cross-β structure.[3, 4, 5, 6, 7, 8] The spectroscopic properties of ThT in amyloid are consistent ThT dimer formation.[9, 10, 11] We discussed that a single β-LGA could bind two ThT molecules creating a small amount of dimer signal, as was shown by intercalation of ThT in γ-cyclodextrin (γ-CD).[10, 11] Because of the potential confounding effects of ThT-bound monomer, time-resolved luminescence evolution of aggregating β-LGA (see Fig. 3.5) was not explicitly discussed. However, a γ-CD / ThT control experiment was performed in Fig. 7.2 to help understand the lifetime distribution of under the initial conditions.
Figure 7.4: *GIPG fit parameters to a urea titration of βLGA.* The blue circles, squares or triangles track along the decay times consistent with the characteristic spherical particle hydrodynamic radii (R_H) of 1, 2, or 3 nm, respectively, as the urea concentration is increased. Note that the particle size distribution is the widest at about 5 M urea. Secondly, we point out that upon going from 0 M to 2 M urea, the R_H becomes smaller implying that the native dimer has been disrupted by denaturant.

7.4   Urea titration of β-LGa

Urea titration was useful to control for understanding the partially denatured states of β-LGA. In chapter 3, ANS multi-peaked "fingerprint" analysis required the use of day 0 βLGA / ANS control (Fig. 7.3). Specifically, the control was used to assign the first fingerprint describing lifetime distribution of the various monomeric and monomer-like components. By increasing the urea concentration, the nature of the different binding modes were easier to elucidate. Also this control helped to understand the binding site reversibility in the ANS reversibility assay. Upon introducing the protein back into native conditions, we could comment on the reversibility of the binding sites depending if the lifetimes resembled a partially denatured or native-like environment.

The DLS measurements showed that the protein had swelled and had a broad

distribution of hydrodynamic radius. In a titration from 0 M to 7 M urea (Fig. 7.4), the width of the DLS R_H distribution was broadest at 5 M urea. Since the width of the distribution was resolvable, this implied the exchange time within that distribution was longer than the characteristic diffusion time of ~20 μs for the monomer. Amyloid formation from βLGA has been observed to be fastest at 5 M urea.[7] The day 0 DLS results showed that the conditions giving the maximum rate of amyloidogenesis were coincident with those that created the maximum variance in the hydrodynamic radius of βLGA.

Chapter 8

Explanation of Global Regularization Code

8.1 Summary

In this chapter, the computational set up and implimentation of the globally regularized interior point gradient method (GIPG) is described. First, the code is introduced and the options are described. Next, there is an explanation of the fast regularized GIPG using three dimensional matrix multiplications. This procedure decreased overall computation by at least an order of magnitude, as compared the method described in chapter 2. Flow charts are provided to help navigate through the IGOR source code. The code itself is written in IGOR 6.03 format and found chapter 9.

8.2 Introduction

Globally regularized interior point gradient method (GIPG) [1] was developed using IGOR Pro (WaveMetrics) platform. IGOR was chosen due to its built in curve-fitting capabilities, ability to handle large data sets, implimenation of fast matrix operations (LAPACK libraries), high speed data displaying and user programming environment which allows for automation. Throughout this chapter, we employ a few terms from the IGOR vernacular, including the terms "wave" (short for waveform) to describe single column array of numbers contained in the rows, matrix to describe waves with multiple columns, and 3D matrix as a matrix with multiple layers. Lastly, the term x-scaling refers to abscissa values

corresponding to a wave if plotted on the ordinate.

GIPG only requires three inputs: the data, a design matrix, and number of iterations. However, the typical GIPG user may prefer set up options to expedite the implementation GIPG for a host fitting applications. IGOR's pop up menu capabilities serves as a useful tool for entering inputs such as:

- data

- options

- parameters.

To run the globally regularized IPG code, one must include the data which is to be fit and a set of basis functions to fit them. The basis functions can be supplied as either a set of "fingerprints" or as a grid of exponentials. For global fitting, the data must be supplied as a matrix, with each column of the matrix representing a single data transient. The order of the data waves within the data matrix should correspond to a continuity condition that the GIPG algorithm implies. Secondary data inputs include instrument response functions matrix and shift constants wave (for convolution of data), standard deviations matrix and x-scaling wave of the data. For secondary data matrices, their columns should match the corresponding columns in the data matrix.

GIPG has already been utilized to globally fit time-correlated single-photon counting [2], temperature-dependent Stokes-shift steady state fluorescence [3], dynamic light scattering [2] data sets. Deconvolution of circular dichroism or infrared absorption spectra also can be fit using regularized GIPG if altering an experimental variable results in a continuity of the fit parameters. Several options have been made available to facilitate the general applicability of fitting a variety of spectroscopic data sets. The options include:

- setting the standard deviations equal to the square root of the data,

- invoking the Seigert relation for IPG fitting homodyne dynamic light scatting data,

- convoluting of a fingerprint matrix by a grid of exponential functions,

- regularizing using linear or quadratic continuity condition or local maximum entropy method,

- selecting a range of grid points to regularize,

- fitting locally or globally,

- pre-normalizing data and standard deviations,

- calculating effective free parameters,

- estimating time to complete fit,

- and/or saving the fit results.

These options should allow for fitting various data set types using different methods. In chapter 3 of this thesis, there are examples of regularized GIPG fitting with some of these options implemented. For example, Seigert relation was used to globally fit the dynamic light scattering data of an aggregating protein along a timecourse. Time-correlated single-photon counting was used to measure evolution fluorescence lifetime distributions of an extrinsically labeled protein over time. The data was first fit using a grid of convoluted exponential decays to obtain a set of lifetime distribution fingerprints. The data was then fit using instrument response convoluted fingerprints to generate a global model of reduced parameters. Maximum entropy method was added by popular demand. It utilized IGOR's built in curvefit capabilities. Unfortunately, it is unstable for large data sets (several hundred parameters) and is to be used at your own risk.

The user must set a few parameters before the fit can be started. They include:

- strength of regularizer

- number of iterations

- size of each IPG step

- and number of display updates.

Once the fitting has started, there are several displays for user evalution, such as,

- a fit window containing the x-scaled data, the fit, calculated reduced chi-squared (χ_r^2), change in χ_r^2, and a counter for the remaining updates

- fit parameters vs basis function coordinate

- and plot of χ_r^2 and probability-to-reject vs update number

GIPG (and for that matter, IPG) is an iterative fitting method without an explicitly defined convergence criteria. Instead, the user inputs the number of iterations to perform. After completion, the user decides if the fit has converged. For convenience, the algorithm displays useful parameters mentioned in the list above, and greater detail in chapter 2 of this thesis. Many users may decide that if χ_r^2 is close to 1.0, and/or the change of χ_r^2 is very small, and/or probability-to- reject < 0.5, the algorithm has converged.

8.2.1 Fast GIPG

Recall the minimization principle in Methods section of chapter 2,

$$(\mathbf{A_l^T A_l} + \gamma \mathbf{H})\mathbf{x_l} - \mathbf{A_l^T b_l} = 0, \tag{8.1}$$

where $\mathbf{A}_l$ is a design matrix for a local data transient, and $\mathbf{H}$ is the regularization matrix,

$$\mathbf{H}^{[K \times K]} \equiv \begin{pmatrix} 1 & -2 & 1 & 0 & 0 & 0 & 0 & \cdots & 0 \\ -2 & 5 & -4 & 1 & 0 & 0 & 0 & \cdots & 0 \\ 1 & -4 & 6 & -4 & 1 & 0 & 0 & \cdots & 0 \\ 0 & 1 & -4 & 6 & -4 & 1 & 0 & \cdots & 0 \\ \vdots & & & & \ddots & & & & \vdots \\ 0 & \cdots & 0 & 1 & -4 & 6 & -4 & 1 & 0 \\ 0 & \cdots & 0 & 0 & 1 & -4 & 6 & -4 & 1 \\ 0 & \cdots & 0 & 0 & 0 & 1 & -4 & 5 & -2 \\ 0 & \cdots & 0 & 0 & 0 & 0 & 1 & -2 & 1 \end{pmatrix}. \tag{8.2}$$

The GIPG algorithm can gain more than an order of magnitude faster computation time by rearranging and recasting the left term in Eq. 8.1, as compared to the GIPG version first presented in Chapter 2. By invoking three dimensional matrix operations and a single transpose step, many pointless zero-zero multiplications can eliminated. For pedagogical purposes, matrix and vector diagrams are utilized to help visualize the conversion to three dimensional matrix operations. Figure 8.1 shows the first term in equation 8.1. In general, dimensions of all the arrays shown in the figures were rendered to be consistent with the text.

When global regularized IPG is used, the global regularization matrix $\mathbf{G}$ (see Eq. 15 in Chapter 2), replaces $\mathbf{H}$ in Eq. 8.1,

$$(\mathbf{A}^{\mathrm{T}}\mathbf{A} + \gamma\mathbf{G}) \times \mathbf{x} - \mathbf{A}^{\mathrm{T}}\mathbf{b} = 0. \tag{8.3}$$

The distributive property can be conjured to split Eq. 8.3 into two terms,

$$\mathbf{A}^{\mathrm{T}}\mathbf{A} \times \mathbf{x} + \gamma\mathbf{G} \times \mathbf{x} - \mathbf{A}^{\mathrm{T}}\mathbf{b} = 0. \tag{8.4}$$

The right expression in Eq. 8.4, visualized in Fig. 8.2, can be rearranged in three dimensions by "folding" each $\mathbf{A}_l^{\mathrm{T}}\mathbf{A}_l$ design matrix along the block diagonal

$$\left(A_\ell^{\mathsf{T}} A_\ell \;+\; \gamma * H \right) \times x_\ell \;-\; A^{\mathsf{T}} b \;=\; 0$$

Key

Number of Grid Points, K $[K \times K]$

H **Regularizer matrix** Colors denote the diagonal, 1$^{\text{st}}$ and 2$^{\text{nd}}$ off-diagonals

$[K \times 1]$

x_ℓ **Parameter vector** Colors represent a parameter set of for each data transient, ℓ
Figure 8.1: *Pedagogical diagram and key for matrix operations.* A key is provided as to link the components of the diagram with mathematical expression in the text. The details of the design of these matrices and vectors were described in Methods section of Chapter 2 under *IPG Regularization.* The bracketed values are the dimensions of the matrices/vectors used.

of $\mathbf{A}^{\mathrm{T}}\mathbf{A}$ into Y layers, to generate a $K \times K \times Y$ 3D matrix. The global parameter vector, $\mathbf{x}$, must also be rearranged as shown in Fig. 8.3.

In order to reduce the total number of zero-zero multiplications, a similar rearrangement as shown above can be performed upon $\mathbf{G}$, however, a transpose is also required. Note that the regularization components represented are in the diagonals components of the off-diagonal blocks in $\mathbf{G}$. The regularizer structure can be set up with K layers and each layer is a $Y \times Y$ $\mathbf{H}$ matrix. Each layer represents a single parameter over the evolution coordinate. Similarly, the global parameter vector needs to be arranged accordingly. For example, the first layer of the $\mathbf{x}$ is the first fit parameter of each data transient. The second layer is the
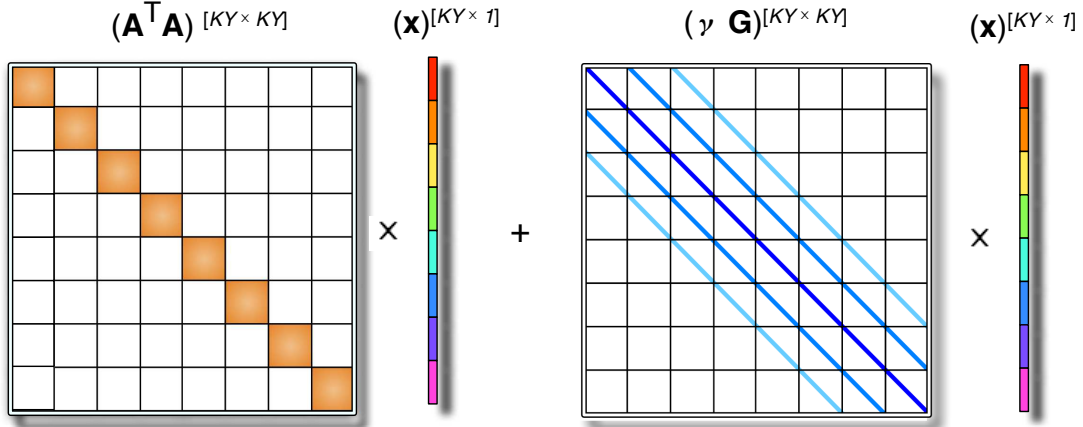

Figure 8.2: *Visual representation of Eq. 8.4* The "white space" are zeroes and the black grid lines are demarcate $K \times K$ matrices. The right vector represent the concatenated parameter waves represented by different colors for each data transient.
Figure 8.3: *The first two terms in Eq. 8.4 is represented pictorially in 3D matrix format.* All of the local $\mathbf{A}_l^T \mathbf{A}_l$ and $\mathbf{x}_l$ are layered for each data transient. The second term includes the global regularization matrix transposed such that each layer represents the a set of parameters that are *a priori* thought to be continous along the experimental domain.

second parameter of each transient, and so on. In order to add the two halves of Eq. 8.4, a transpose is necessary with each GIPG iteration. This step is insignificant to the brute force matrix multiplication of Eq. 8.3 for large GIPG problems.

8.3 Flow charts

Flow charts were developed to help user understand the actions of the source code. Fig. 8.4 shows the overall structure of the GIPG, including a key which is applicable to all of the subsequenct schemes. Colored boxes point to highlight very important steps. Fig. 8.5 describes the setup of the relevant design and regularization matrix depending on type of basis functions chosen. Also, this is where the appropriate data, standard deviations, and x-scaling waves are prepared. Setup Reg Part1 in Fig. 8.6 is potentially slowest step of the GIPG algorithm. Normalization and calculation of the effective free parameters are also performed.

Curriculum Vita

Jason Thomas Giurleo

Education

1995   Graduated from Hackensack High School, Hackensack, NJ

1999   B. S. in Chemistry (Minor: Physics) from The College of New Jersey, Ewing, NJ

2008   Ph. D. in Chemistry and Chemical Biology, Rutgers, The State University of New Jersey, Piscataway, NJ

Employment

1999-2001 Chemist, Hoffmann-La Roche, Nutley, New Jersey

2001-2003 Teaching assistant, Department of Chemistry and Chemical Biology, Rutgers University

2003-2004 Molecular Biophysics Trainee, Department of Chemistry and Chemical Biology, Rutgers University

2004-2006 GAANN Fellow, Department of Chemistry and Chemical Biology, Rutgers University

2006-2008 Graduate assistant, Department of Chemistry and Chemical Biology, Rutgers University

Publications

2006   T. C. Messina, H. Kim, **J. T. Giurleo**, and D. S. Talaga, "Hidden Markov Model Analysis of Multichromophore Photobleaching", *J. Phys. Chem. B* **110**, 16366-16376 (2006) DOI: 10.1021/jp062192b

2008   **J. T. Giurleo**, Xianglan He and D. S. Talaga, "β-lactoglobulin assembles into amyloid through sequential aggregated intermediates", *J. Mol. Bio.* **381**, 1332-1348 (2008) DOI:10.1016/j.jmb.2008.06.043.

2008   Jeremy Pronchik, **J. T. Giurleo** and David S. Talaga, "Separation and Analysis of Dynamic Stokes Shift with Multiple Fluorescence Environments: Coumarin 153 in Bovine β-Lactoglobulin A", *J. Phys. Chem. B* **112**, 11422-1434 (2008) DOI: 10.1021/jp802666n

2008   **J. T. Giurleo** and D. S. Talaga, "Global fitting without a global model: Regularization based on the continuity of the evolution of parameter distributions", *J. Chem. Phys.* **128**, (2008) DOI:10.1063/1.2837293.
