ABSTRACT OF THE THESIS AN OPTIMIZATION-SIMULATION APPROACH FOR LOCATING WAREHOUSES IN LOGISTICS NETWORKS by AYBERK ONUR GOKSEVEN

Thesis Director:

Professor Mohsen Jafari

This thesis introduces a hybrid optimization-simulation model to locate international and regional warehouses for importer companies. The model assumes multiple products, one or two ports of entry, several geographic regions for the continental US, two international warehouses (IWH) and six regional warehouses (RWH). Demand and transit times are assumed probabilistic and several inventory control mechanisms are assumed. Certain cost based constraints for warehouse locations are included in the model. We conducted many experiments and our observation has been that the warehousing location assignments follow a branching pattern starting from the port of entry and stretching towards downstream echelons. The segments of these branches, meaning distance between Port-IWH or IWH-RWH pairs, get longer or shorter depending on the transportation cost inputs of the model. Basically, in order to minimize the overall

transportation costs, the optimization model searches for a solution to balance the cost ratio between these segments. According to our model, warehousing cost and demand distribution appear to be important factors for selecting warehouse locations in the logistics network. If there are multiple potential neighboring regions, the optimization model normally chooses the low-cost region. However, when these regions are similar to each other according to the warehousing cost, the model seeks for a location which is closer to the high-demand regions.

Preface

A generic simulation tool has been developed in order to study the logistics network of importer companies. Multiple scenarios were experimented based on different combinations of port of entries, transportation modes, import volume distributions and warehousing costs.

This thesis is organized as follows. Chapter 1 makes a brief introduction to the logistics networks, represents the objective of this thesis and then reviews the past literature about facility location problems. Chapter 2 provides detailed information about logistics networks of importer companies, such as, ports, warehouses, customers and modes of transportation. After that, Chapter 2 continues with the factors that affect the site selection problem of warehouses. Chapter 3 talks about the problem approach followed by this thesis and then discusses the proposed model in two sections as: 1) simulation model, and 2) optimization model. Chapter 4 talks about the general scenario designed for this thesis and then introduces the proposed model inputs. This is followed by the representation of experimentation methodology together with the discussion of results in Chapter 5. Chapter 6 summarizes this thesis and represents conclusions together with improvements for future work. Appendix A, B and C represent the inputs used in developing the experiments and provide detailed information about these inputs. Appendix D provides information about the simulation template. Finally, Appendix E represents a sample output data for both simulation and optimization models.

Chapter 1

Introduction and Literature Review

The Council of Supply Chain Management Professionals (2006) defines logistics as "the process of planning, implementing, and controlling procedures for the efficient and effective transportation and storage of goods including services, and related information, from the point of origin to the point of consumption for the purpose of conforming to customer requirements". This includes inbound, outbound, internal, and external movements. The overall worldwide logistics-related expenses were \$3.4 trillion for 1996 (Gourdin, 2006) – with the North American share of 27%, European Union share of almost 28% and Asia/Pacific Nations share of about 19%. Generally speaking, the cost elements in a logistics network can be classified into three groups: transportation, inventory and administration costs. Transportation and inventory costs are usually about 80-90% of the total logistics cost, both are related to location of facilities. By properly selecting facility locations, companies try to reduce costs of their logistics.

The objective of this thesis is to develop a tool to help companies in making their warehouse location decisions and understand certain factors that has crucial effect on this location problem. In particular, we developed an optimization-simulation approach for optimal location of warehouses to a predetermined set of alternative locations. We focus our attention to industries that are mainly in the import business. Here, we take into consideration the material flow from the point of importation up to delivery to customers.

1.1 Literature Review

According to Gourdin (2006), "most comprehensive facility location techniques fall into one of the following categories: optimizations, simulations or heuristics". Below we will summarize the early work in these areas.

An early work on optimizing warehouse locations can be found in Baumol and Wolfe (1957). In this paper, location problem was handled as a standard transportation problem with an objective of minimizing total delivery cost. Their model had the following major features: (1) Cost variables could be nonlinear functions. (2) Capacity constraints were included in the model. Despite the fact that they were talking about the presence of warehouse capacity constraints, their solutions ignored these restrictions. (3) Shipment quantities from factories (suppliers) were related to the warehouses on their way to the retailers. Baumol and Wolfe claimed that, generally speaking, there were no useful computational procedures to calculate the definite least possible amount of a concave cost function.

Khumawala (1972) introduced mixed integer programming formulation of the warehouse location problems with an efficient branch and bound algorithm. According to Khumawala, Effroymson and Ray (1966) had earlier applied branch and bound technique to calculate optimal solutions for warehouse location problems. But, his technique is drastically more efficient, as he put it. The first improvement was setting a branching decision rule at every level in order to select an available warehouse location from the overall set of available locations. The second improvement was about managing the integer variables. Initially, by using this technique the algorithm was solved as if it was a linear program.

Mixed integer programming was revisited by Melachrinoudis and Min (2007). This time the objective was to redesign a warehouse network in order to minimize total supplychain cost including production, transportation, warehousing and relocating costs, and at the same time to maximize the closure and/or consolidation of the unnecessary warehouses. In other words, the program was constructed in order to optimize a given warehouse network by simultaneously eliminating redundant (existing) warehouses and locating new potential warehouse. Their mathematical formulation took into account certain restrictions such as: production capacity of the plants, supplying of all customer demand and serving every customer in a given time frame.

Related work about simulation techniques for warehousing networks can be found in Williams and Gunal (2003). This study presented a general summary about a commercial logistics simulation software package, called SimFlexTM. As a matter of fact, this software tool was claimed to be capable of dealing with location, manufacturing, transportation, procurement, distribution, sales and tradeoff problems. In the given case study, manufacturing facility and distribution center locations were specified to the model with inventory control policies and customer demand data. Furthermore, product types and their hierarchical constituent particles were fed along with logistic services and

delivery policies. Some other variables were also allowed in the model, such as, processing times and shipment costs.

Another way of approaching warehouse location problems is to combine optimization techniques with simulation modeling in order to utilize their specialties altogether. A related work about designing distribution networks was presented in Ko, et al (2006) with a hybrid optimization-simulation approach considering the warehouses' performance. A genetic algorithm was used in the optimization model to locate storage space to various locations depending on their demands at different points in time. A simulation model was used to generate stochastic demand and time components.

In this thesis, we built on the model developed by Ko, et al (2006) by incorporating inventory control policies into facilities and thereby controlling the product flow in the logistics network. In the end, we came up with a simulation model which is capable of modeling most of the important aspects of this logistics network including ports, international warehouses, regional warehouses and customer market.

Chapter 2

Problem Definition

By definition, an importer can be a legal entity, form or an individual which brings merchandise from a source outside the country into a domestic market through commercial means. In this thesis, we focus on the logistics networks arising in the supply chains of importer companies (as shown in Figure 2.1). We assume that the logistics network spans from the supplier all the way to the delivery of the product to the customer. Nodes of such logistics network may consist of ports, warehouses and customers, and transportation modes in between. In this section, we describe the key components to provide a foundation for the idea of logistics network under the study in this thesis.

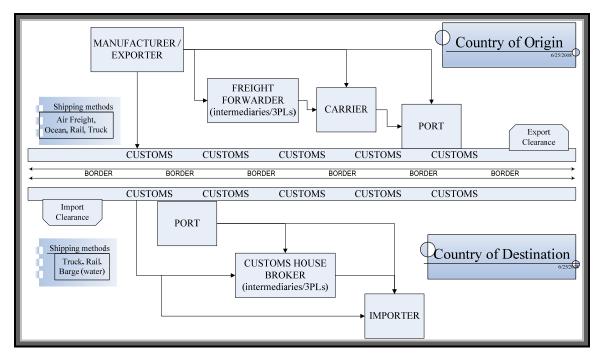

Figure 2.1: A typical supply chain for an importer company

2.1 Ports

Ports (seaports) are the facilities for receiving ships and transferring cargo. For our model, ports are the only point of entries for the imported merchandise. They constitute important nodes where cargo experiences delays in the logistics network. Ports receive shipments and store them until a convenient mode of transportation becomes available. The arrival time and the amount of shipments can be based on schedules, and moreover stochastic transit times may be added to the port logic. Furthermore, the cost issues associated with ports can be included into the system in terms of handling costs per shipment, port fees and taxes. These cost parameters can be used to calculate overall port expenses in the network.

2.2 Warehouses

Warehouses are commercial buildings for storage of goods. Two types of warehouses are considered in the logistics model: international and regional warehouses. The usual scenario is the transportation of goods from ports to international warehouses (IWH) and then from international warehouses to regional warehouses (RWH).

International warehouses are the main (primary) storage facilities for the importer company within the country of destination. All of the imported merchandise is being transported to associated international warehouses through the ports. In addition to the stock keeping property, these warehouses may also be responsible for various value added operations, consolidation and deconsolidation of the shipments. Nonetheless, their primary objective is to replenish inventory levels of the regional warehouses. Regional warehouses are considered to be much smaller in size compared to international warehouses. Their primary objectives are keeping local inventory and supplying the market demand in acceptable time frames.

Inventory control policies for these warehouses are based on periodic review with inventory positioning. Simply put, if the inventory position goes below the re-order level for each time the inventory is reviewed, an order is created for the required amount of the product. There is also the concept of safety stock which represents the buffer stock for compensating delays in supply-chains and variation in customer demand.

2.3 Customers

Customers constitute the demand for products in our logistic network. In this study, we represented customers by regions (i.e., clustered markets). According to Jain and Dubes (1988), the description of a cluster is "connected regions of a multi-dimensional space containing a relatively high density of points, separated from other such regions by a region containing a relatively low density of points". Furthermore, clusters may be defined as the division of entities in groups based on some aspects of the entities' characteristics (Anderberg, 1973). These definitions are used to determine the clusters in the network. Each cluster is representing a given region that has its own demand distribution which symbolizes the market enclosed by that region.

2.4 Modes of Transportation

Possible transportation means that can be used in between echelons are air freight, shipping, trucking and rail. For the sake of simplicity, we are going to implement some of these transportation methods into the model. Between product origin and port of entry, the transportation method was set to shipping. Trucking and rail are the two common methods for inland transportation. Therefore, transportation between ports and international warehouses is set to be made by rail and/or trucking services. Only trucking service was implemented into the model in between warehouses and warehouse-region pairs.

2.5 Site Selection Problem

Globalization has enormous impacts on the operations of any company. To be profitable in global markets, companies must optimize their manufacturing and supply-chain operations. In supply-chain (logistics) systems, site selection problem is important since it directly affects transportation and labor costs as well as the speed of moving products from ports to their final destinations. Most of the logistics related costs such as transportation, distribution and product handling are somewhat related to warehouse locations. According to LaLonde and Delaney, transportation costs, which are related to the movements of goods from product origin to storage and to final destination, account for approximately 50% of the total logistics cost, and about 30% of the total logistic costs are due to the direct warehousing costs (cited in Sivitanidou, 1996). Clearly for supplychain (logistics) systems, site and capacity selection is one of the important decisions, involving cost, credibility and pace, in the long-term planning of a company.

Reliability or credibility as well as speed are also very important. Basically, the distribution process should be as reliable and fast as possible. Especially with the implementation of "just in time" inventory strategies companies are willing not to keep excess inventory before it is needed. Therefore, they are expecting to have flawless (and punctual) logistics networks. According to Strategic Distribution Business Promotion Plan (SDBPP) (2007), some of the Top 100 Importers and Exporters (from Journal of Commerce, 2005) are serving their markets within a range of one to two days, and some of these companies are willing to pay more to save days out of the transportation time.

Under these circumstances, identifying favorable warehouse locations -in terms of cost, credibility and pace in the logistics network- turns out to be a very crucial aspect for retail businesses. The overall supply-chain network should be designed considering the key factors listed above.

2.6 Factors Effecting Site Selection Decisions

This section is going to define cost, proximity, availability and regulation factors which affect warehousing network decisions.

2.6.1 Cost Factors:

Gerry Shear emphasizes the importance of cost factor by stating the transportation cost as "the biggest cost associated with distribution. The cost of outbound distribution to stores is entirely the retailer's responsibility and the placement of the distribution center is a very important factor in managing these costs" (cited in "Site Selection for DC's", 2003). Transportation costs might be a significant element of the entire cost factor; however, there are other cost elements like holding, ordering, shortage costs which form the **total inventory cost**; and labor, facility, administrative, equipment costs which form the **total warehousing cost**. "Logistics Costs and US Gross Domestic Product" (2005) presents the estimates of US business logistic costs for 2002, and states that about 33% of the total logistics costs constitutes inventory-carrying (including warehousing) expenses.

2.6.2 <u>Proximity Factors</u>:

Proximity issues are not so different from the cost factors for selecting the warehouse location. The necessity for being close to certain regions arises due to the need of reducing transportation and/or inventory costs. Companies are willing to locate their warehouses depending on the proximity to the source or the consumer.

2.6.3 <u>Availability Factors</u>:

After cost and proximity factors for selecting warehouse locations, we can talk about availability factors' of certain services and resources. Basically, these constraints include availability of qualified labor, transportation means and specialized services.

2.6.3.1 Availability of Labor,

According to Gil Mayfield, being close to the appropriate working force (class) is the most crucial component for selecting the location of warehouses (cited in "Site Selection", 2003). Unfortunately, labor availability can change drastically within even short distances. As a result of this, site selection gets an important restriction over most of the available regions. In some cases, companies choose to recruit and train their own work forces due to the difficulties of finding qualified labor around a probable warehouse location. As a result of additional trainings and recruiting processes overall labor cost increases unfavorably. According to Rena Sivitanidou (1996, p. 1261), facility location problems have constraints of both low and high skilled labor, and this has to be satisfied in a given region. We can conclude that defining labor constraints is an essential part for optimization of the warehouse location due to its complex cost, availability and quality variations.

2.6.3.2 Availability of Transportation,

The requirement for means of transportation is simple; warehouses need to be accessed by different types of transportation modes, such as land, water or air shipment. Among these, rail system can play an important role for the selection of warehouse location. In most cases, rail systems offer cheaper and more consistent way of transportation (this statement is questionable regarding to the inconsistencies of the rail system in US). On the other hand, flexibility of an available transportation system is also essential. In other words, inbound and outbound transportation required to be (easily) responsive to changes in shipping locations. As a result, locations which have the access multi-modal transportation happen to be more favorable for some companies.

2.6.3.3 Availability of Services,

Besides availability of skilled labor and transportation means, availability of specialized services can be very important in some logistics network. These are services provided by intermediaries or third party logistics (3PL) providers and include transportation, warehousing and logistic services. The reason for outsourcing is clearly stated by Long (2003): "competitive pressure has made many companies return to their core competencies and outsource functions that others can do better". In other words, if the benefits of outsourcing to another company are greater than the cost of supervising that company, then those services should rather be outsourced.

2.6.4 <u>Regulation Factors</u>:

At this point, we are considering governmental codes that regulate transportation, warehousing and environmental issues. Implementation of free trade zones (FTZ), which lowers general trade barriers and bureaucratic requirements, can be stated as an example for the beneficial regulations. A good reference can be represented from SDBPP (2007); one of the interviewed companies claimed that by using FTZ, they have been saving annually 5% of their inventory cost through postponing duty taxes until selling their products.

Chapter 3

The Proposed Approach

This thesis considers a single company that is planning to optimize its logistics network. We handled the problem by developing a hybrid optimization-simulation model that searches for an optimum or near optimum warehousing network. The simulation part of the model is capable of replicating logistics network of a given company, including its suppliers, ports, warehouses and customer market. We have implemented certain cost, demand and transportation variables into the simulation model which is capable of managing multiple products. The optimization part of the model searches for an optimal networking decision by generating various warehousing scenarios for the simulation model. These scenarios are simulated and their results are compared automatically by the optimization part. In additional to that, modelers are capable of setting certain constraints for warehouse locations and cost parameters via optimization model in order to control the optimization mechanism.

3.1 The Simulation Model

To simulate the logistics network, a logistics template was developed by using Arena Simulation Software. With this Template, we are capable of modeling a wide variety of logistics networks for any given importer company. Below, we mention about the implemented logic behind this template which was used to create the simulation model. The logistics network model consists of five echelons: customers, regional warehouses (RWH), international warehouses (IWH), ports and suppliers. The hierarchical outline of the model is given in Figure 3.1, and a representative scenario for a logistics network is shown Figure 3.2. According to these figures, each node is connected to one and only one upper node. This implies that at every stage, the order requests will be directed to only one node at the upper stream. Nevertheless, any of these nodes (excluding the final one, customers) might supply multiple lower nodes.

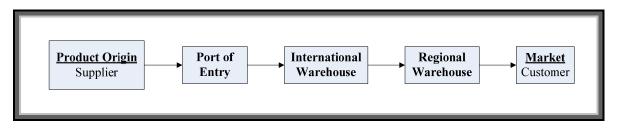

Figure 3.1: Hierarchy of a logistics network

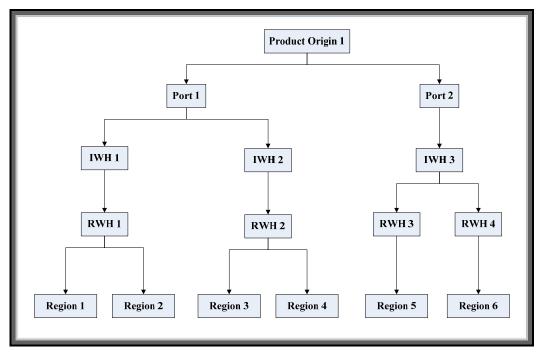

Figure 3.2: Scheme of a representative scenario

The constructed logic behind these nodes is capable of simulating a logistics network, and calculating expenses based on transportation, warehousing and inventory parameters. Figure 3.3 represents the architectural relationships between nodes of a logistics network, and specifies fundamental variables and control parameters associated with it.

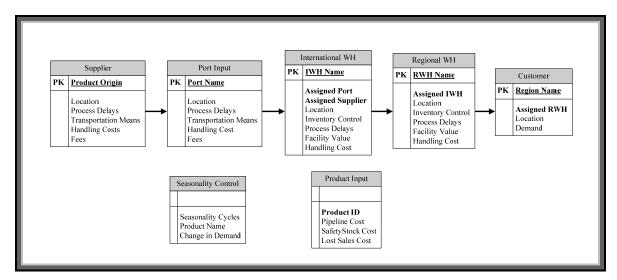

Figure 3.3: Arena module relationships

The following section contains the basic but yet crucial information about the warehousing logic. Detailed information regarding to all nodes (echelons), including product origin, ports, warehouses and regions is given in Appendix D.

3.1.1 <u>Warehousing Logic</u>:

The implemented logic in warehouse objects consists of two sections: supplying demand and controlling inventory. An overview of the supply logic is shown in Figure 3.4. When an order arrives, if the warehouse has enough stock to supply the demand, then the supplying mechanism will be instantly initiated. However, if there is not enough stock to supply the total demand of one or more products, then, depending on the inventory onhand, these orders are going to be either partially supplied or dismissed completely. When an order is supplied, the equivalent amount of inventory is deducted from both onhand inventory and inventory position levels. The final stage for this procedure is to prepare a shipment plan which includes type, duration and cost of transportation.

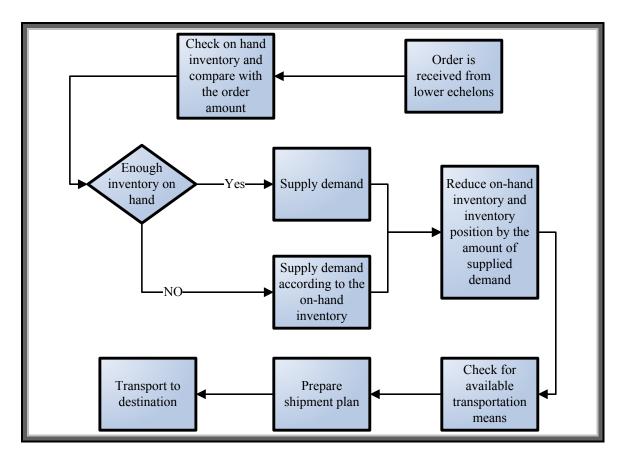

Figure 3.4: Supply logic for warehouses

Every warehouse has its own inventory control policy. A general (r, R) policy, with a safety stock level, is implemented at each warehouse. Basically, inventories will be checked on pre-set review periods, and whenever inventory position goes below re-order level (r), an order will be prepared for an equivalent amount of product to move the

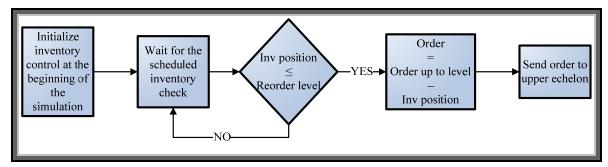

Figure 3.5: Inventory control logic

inventory position to order up to level (R). This process is shown in the Figure 3.5. Within the constructed logistics template, these variables can either be entered manually via each warehouse's dialog box or set to be calculated automatically within the template's logic. The equations used for the calculations are explained below:

Notation for Parameters:

- SS (i) Safety stock for product i (in units of TEUs).
- RoL (i) Re-order level for product i (in units of TEUs).
- OuL (i) Order up to level for product i (in units of TEUs).
- Inv (i) On-hand inventory for product i (in units of TEUs).
- IP (i) Inventory position for product i (in units of TEUs).
- c Correlation factor (accepted to be 0.5).
- D (i) Demand for product i per unit amount of time.
- D_i Demand for product i during review period.
- σ_i Standard deviation of demand for product i.
- F Frequency of shipments.
- f Standard deviation factor.

- K Safety factor (take k = 2 for 98% of no stock-outs).
- LT Lead time for receiving orders (between ordering goods and receipt at destination).
- σ Standard deviation of lead time.
- T Review period.
- ST Safety time.

The following equations are used for the calculations of the safety-stock, re-order and order up to levels for any given warehouse. These equations are based on lead time values between nodes and demand parameters of the lower echelon. For the computation of these proposed inventory parameters, we have implemented two different set of calculation methods as Type-1 and Type-2. The modeler can choose the one that is more suitable for the studied scenario.

Type-1 Calculations⁽¹⁾:

Formula for Safety Stock

$$ST = LT + f \times \sigma \tag{1}$$

$$SS(i) = \sigma_i \times ST \tag{2}$$

Formula for Re-order Level

$$RoL(i) = \frac{LT \times D_i}{T} + SS(i)$$
(3)

Formula for Order up to Level

$$OuL(i) = \frac{D_i}{T} + RoL(i) \tag{4}$$

⁽¹⁾ This set of calculations is based on Reference 14.

<u>Type-2 Calculations⁽²⁾</u>:

Formula for Safety Stock

$$SS(i) = k\sqrt{(LT+F) \times \sigma_i^2 + [D(i)]^2 \times \sigma^2}$$
(5)

Formula for Re-order Level

$$RoL(i) = (LT + F)^{c} \times D(i)$$
(6)

Formula for Order up to Level

$$OuL(i) = RoL(i) + D(i) \tag{7}$$

<u>Note</u>: We have not set frequency of shipments (F) in the logic of the template; therefore, we are going to ignore it from these equations.

Initial inventory position and on-hand inventory levels for both calculation types:

$$Inv(i) = \frac{RoL(i) + OuL(i)}{2} = IP(i)$$
(8)

3.1.2 <u>Cost Parameters</u>:

As stated in previous sections, the simulation model is also responsible for cost calculations. The model is designed for the calculations of cost parameters of product origin, port, warehouse, inventory and all transportation costs in between. At the end of each run, the total cost figures will be calculated according to the inputs of cost elements. These proposed elements can be inputted to the model individually or together. The breakdown of cost elements are listed below:

⁽²⁾ This set of calculations is based on Reference 10.

Ports & Product Origin	Warehouses	Inventory	Transportation
Handling	Facility	Safety-Stock	Trucking
Taxes	Labor	Pipeline	Rail
Other fees	Equipment	Ordering	Shipping
	Utilities	Shortage	
	Taxes		

Table 3.1: Implemented cost parameters in the simulation model

3.2 **Optimization Model**

The general optimization problem is based on minimizing the total cost output of the simulation model. In a given scenario, there might be *i* IWHs and *j* RWHs that serve the overall market. Each warehouse is going to be located within a given set of potential regions. If we set each region with a unique ID number, we can input its location as a constraint to the optimization model. If the output of the model that we seek to minimize is Q, the optimization problem can be formally stated as,

$$\min_{IWH1,\ldots,IWHi,RWH1,\ldots,RWHj} E[Q(IWH_1,\ldots,IWH_i,RWH_1,\ldots,RWH_j]$$

Subject to,

We use OptQuest Software for the optimization tool for the designed simulation model. This software is exclusively for optimization purposes and it has the capability of operating with Arena models. The principals of OptQuest are summarized in its manual as:

"The optimization method used by OptQuest evaluates the responses from the current simulation run, analyzes and integrates these with responses from previous simulation runs, and determines a new set of values for the controls, which are then evaluated by running the Arena model. This is an iterative process that successively generates new sets of values for the controls, not all of them improving, but which, over time, provides a highly efficient trajectory to the best solutions. The process continues until some termination criterion is satisfied-usually stopping after a number of simulations or when OptQuest determines the objective value has stopped improving. Its ultimate goal is to find the solution that optimizes (maximizes or minimizes) the value of the model's objective".

This software also allows modelers to set additional constraints for cost parameters and warehouse locations in order to control the optimization criteria. It is used to search for an optimal networking decision by generating multiple warehousing scenarios for the simulation model. By comparing cost outputs of every scenario, OptQuest searches for the lowest-cost logistics network.

Chapter 4

Logistics Network Model

In this chapter, our intention is to represent an example model that is composed of a single importer company. The goal is to optimize this company's logistics network within the continental United States (excluding Alaska and Hawaii). We have come up with a hypothetical company which is importing three different products from Shanghai, China. The average import volumes are accepted as 20, 10 and 30 thousand TEUs per year for Product 1, 2 and 3. In order to point out the status of this Company, we can state that with such a volume of imports, it can be classified in the Top 25 importer/exporter companies in US. Based on the assumed declared values, we came up with the product related inputs such as pipeline, safety-stock and lost sales costs. Detailed information about preparation of Table 4.1 is shown in Appendix A.

	Product 1	Product 2	Product 3	unit
Declared Value	40	50	30	per cubic foot
Pipeline Cost	56	70	42	per TEU - day
Safety-Stock Cost	67	84	50	per TEU - day
Lost Sales Cost	23000	29000	18000	per TEU

Table 4.1: Product related inputs to the model

Based on the Leachman's report on Port and Modal Elasticity Study, the US market is divided into 19 regions. Detailed information about these Regions and proposed

warehousing locations in these Regions are represented in Appendix A. According to this Study, demand levels are proportional to purchasing power of each region. Therefore, import volume distributions are prepared on the basis of per-capita personal incomes by state and state populations. The following table is accepted as a basis for all products and used for the calculation of mean demand levels, which is presented in Table B.6 in Appendix B.

	Region ID	Region Name	% of Total Imports
1	Region 5	Seattle-Tacoma	4.024
2	Region 6	Oakland	6.629
3	Region 7	LA-LB	11.782
4	Region 8	Minneapolis	3.262
5	Region 9	Kansas City	4.219
6	Region 10	Dallas	4.572
7	Region 11	Houston	5.576
8	Region 12	Memphis	3.765
9	Region 13	Chicago	10.990
10	Region 14	Atlanta	10.323
11	Region 15	Columbus	1.888

19	Region 23	Boston	4.290
		Total	100.000

Table 4.2: Import volume distribution by region

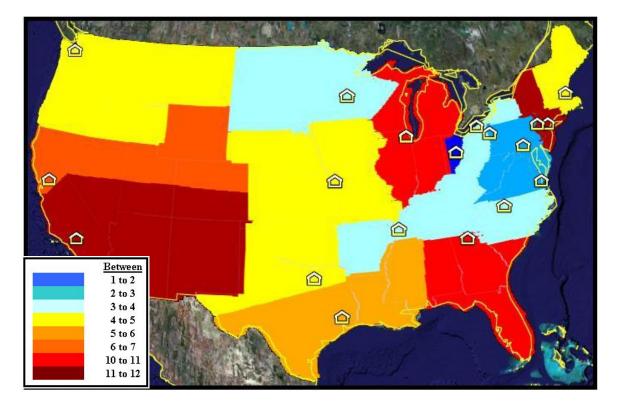

Figure 4.1: Map of import volume distribution⁽¹⁾

Port of entry to the US market is set as either LA-LB or NY-NJ Ports. As the initial stage for storing goods, the Company is accepted to have two international warehouses (IWH) in the site of importation. IWHs are responsible for replenishing inventory of other smaller warehouses, namely regional warehouses (RWH). There are 6 RWHs that are responsible for supplying 19 Regions in US market. Table 4.3 shows the association between IWHs, RWHs and Regions in the proposed logistics network.

⁽¹⁾ All maps presented in this thesis were prepared by Google Earth Software.

		Regions Served (Region ID)	Referred As
IWH 1	RWH 1	5, 6, 7	West Cost Regions
	RWH 2	8, 9, 10, 11	Central-West Regions
	RWH 3	13, 15, 16	Central-East Regions
IWH 2	RWH 4	22, 23	North East Regions
	RWH 5	17, 19, 20, 21	
	RWH 6	12, 14, 18	South East Regions

Table 4.3: Relationships between IWHs, RWHs and Regions

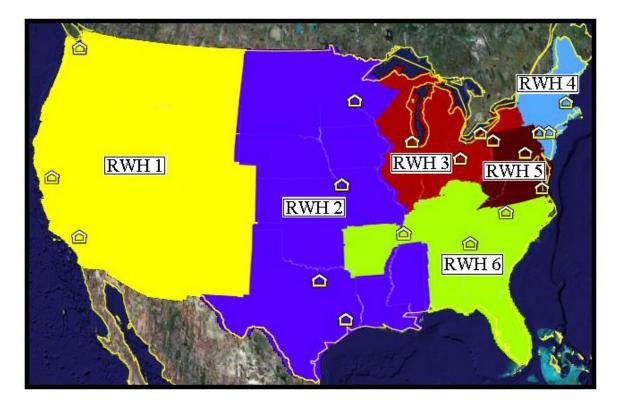

Figure 4.2: US Market divided among RWHs

There is certain cost parameters associated with warehouses such as, facility, handling, ordering and transportation (trucking or rail) costs. These parameters can either be

entered into the simulation model by using variable matrices or entered separately through each warehouse interface.

For the proposed scenario, we accepted The Boyd Company's Report (2006) on "A Comparative Operating Cost Analysis for Distribution Warehousing". According to the article "For Cheap Space, Go South" (2006), Boyd Company has studied overall operating costs for distribution centers in 50 different cities in US. They have included costs of labor, utilities, construction/leasing and taxes for a 350,000 square-foot facility that employs 150 non-exempt workers. The article also represents the most and least expensive locations for having a distribution center. Table below shows the annual operating costs retrieved from this article. We have used this information to derive our warehousing cost input to the model. This data is shown in Table B.4 at Appendix B.

	Operating Costs (\$)
New York	18,204,373
San Francisco	17,453,387
Los Angeles	17,444,428
Nassau/Suffolk, New York	17,256,767
San Diego	17,154,130
Tulsa, Oklahoma	12,232,331
Chattanooga, Tennessee	12,172,960
Birmingham, Alabama	12,120,971
Mobile, Alabama	11,932,829
Little Rock, Arkansas	11,514,935

Table 4.4: Annual operating costs to own a warehouse

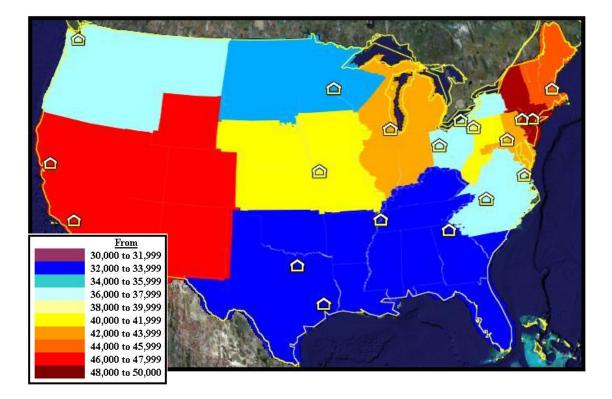

Figure 4.3: Warehousing cost map (legend is based on daily values)

There are two types of transportation methods for inland transportation, rail and trucking:

Rail can only be used between Ports and IWHs. As a basis for preparation of rail transit time inputs, we have accepted "Table 14: Assumed Mean Transit Times for Inland Truck and Rail Movement" from Leachman's (2005) Study. This transit time data represents the overall transportation time including loading at port, unloading and draying at the destination. This data is presented in Table C.2 in Appendix C. The details about preparation of rail cost data is given in the beginning of Appendix C and the results are shown in Table C.3.

Trucking costs, between warehouses, are calculated based on the distance between these nodes which is represented in Table C.5 in Appendix C (light-blue highlighted cells). For 40-foot and 53-foot trucking cost calculations, we have assumed trucking costs as \$2 and \$2.5 per mile, respectively. This assumption is based on Chang's and Canode's Study on "Economic Impact of the Choctaw Point Intermodal Facility on the Mobile Area" (2003). Chang and Canode stated that their calculations were based on Moffatt & Nichol Engineers' datum on trucking cost which is \$1.15 per TEU per mile. Furthermore, we assumed that minimum trucking cost between any two locations, including deliveries in the same region, cannot be lower than \$400 for 40-foot and \$500 for 53-foot containers. For trucking costs between Ports and IWHs (highlighted with grey), we have followed the same procedure for calculating the rail cost. This is also explained in Appendix C together with the calculations of trucking times.

For the inventory control parameters in warehouses, we used "Type-2 Calculation" method which is mentioned in Chapter 3. For IWHs, we defined safety and correlation factors as 10 and 0.5, respectively; for RWHs, these values were set to 6 and 0.1.

The following Table represents the basic data used in OptQuest software. It shows the suggested regions and possible region sets for warehousing locations. Notice that no region set is given for IWH 1. The location of the IWH 1 was defined as a fixed input for the proposed scenarios. This decision helps to drastically lower the number of possible location combinations and further lower the required optimization time. In additional to that, by considering the proximity of the warehousing location in Region 7 to the LA-LB

	Suggested Region	Region Set		
	(initial feed to OptQuest)	Lower Bound	Upper Bound	
IWH 1	7	fixed	l to 7	
IWH 2	13	12	21 or $23^{(3)}$	
RWH 1	7	5	7	
RWH 2	10	8	11	
RWH 3	13	13	16	
RWH 4	21	15	23	
RWH 5	17	15	21	
RWH 6	12	12	19	

Port, we can claim that having an international warehouse in this Region is a fair and valid assumption.

Table 4.5: Location constraints for OptQuest

Based on this Table, we have based the optimization software to minimize the overall cost output of the simulation model. If the output that we seek to minimize is Q, the optimization problem can be formally stated as,

$$\min_{IWH1,IWH2,RWH1,\ldots,RWH6} E[Q(IWH_1,IWH_2,RWH_1,\ldots,RWH_6]$$

⁽³⁾ Upper bound for IWH 2 is set to 23 when NY-NJ Port is being utilized.

Subject to,

Chapter 5

Numerical Experimentation and Results

We have based our simulation runs on 730 days of replication length which is approximately 2 years. In order to fully understand the constructed logistics network, we have generated multiple logistics scenarios and simulation-optimization experiments. These experimentations can be described in three sets:

For the first set of experimentations,

We have used the data provided in the previous section and experimented four scenarios based on two different ports together with two transportation options. In order to serve the entire US Market, only one Port was utilized in the 1st and 2nd models. However, for the 3rd and 4th models, 2 Ports were implemented in the logic, in which, LA-LB Port was assigned for supplying IWH 1 and NY-NJ Port was assigned for IWH 2. Within these two groups, we have also constructed separate scenarios by the input of different transportation methods between Ports and IWHs. The Table below shows all these combinations and their results.

Based on the overall output shown in Table 5.1, we may conclude that instead of serving West Cost Regions by RWH 1, we can supply directly from IWH 1, if desired. Moreover, RWH 2 was suggested to be located in Region 10 in order to serve Central-West Regions. This is due to the low transportation cost between IWH 1 and RWH 2, and low

	Gro	up 1	Group 2	
	Model 1	Model 2	Model 3	Model 4

RWH 1	7	7	7	7
RWH 2	10	10	10	10
RWH 3	15	15	16	15
RWH 4	16	15	21	21
RWH 5	16	18	19 19	
RWH 6	15	12	18 19	
Total Cost ⁽¹⁾	1.195293639	1.267873734	1.097312363	1.121152915

warehousing cost at Region 10. These conclusions are also applicable to Model 12 and 13, see Table 5.2 and 5.3.

<u>Table 5.1</u>: Data of the first set of experimentations⁽²⁾

According to the results of Model 1, if consolidation of regional warehouses is allowed, Central-East and Eastern Regions can be supplied by 2 RWHs, instead of 4. By doing this, the overall cost is expected to be lower than indicated unless warehousing costs increase drastically by the increase in turnover ratio. The overall cost for Model 1 is predicted to be higher than Model 3 and 4. This is mainly due to (the cost of mini-land bridge) the inland transportation cost between LA-LB Port and IWH 2. As the primary mode of

⁽¹⁾ The unit of total cost is in billions of dollars, throughout this Chapter

⁽²⁾ Optimal assignments of IWHs and RWHs to regions

transportation was rail, the goods are transported by rail between Port and IWH 2; and direct-trucking with 40-foot containers between Port and IWH 1.

Model 2 was prepared with a slight modification on Model 1. Instead of utilizing multiple transportation methods through the inland distribution, only trucking was allowed for Model 2. Together with this modification, cross-docking to 53-foot containers was also permitted for trucking between the Port and IWHs (normally, it is only allowed between downstream echelons, starting from IWHs). As expected, the overall logistics cost was calculated to be higher than the previous model. This is mainly because of the high trucking cost (compared to rail) even though the goods were allowed to be consolidated into 53-foot containers. As a result, proximity between Port and IWHs became more crucial and Region 12 was proposed as the location of IWH 2. When it comes to the locating RWHs, warehousing cost also becomes an important factor together with transportation cost. Therefore, RWH 3, 4 and 5 were proposed to be located at closer and cheaper locations. As the last comment on Model 2, we can state that, South East Regions can be supplied directly from IWH 2 instead of operating another RHW, if desired.

By adding another port to the model, the expected logistics cost decreases drastically together with the change in the structure of logistics networks. First of all, even the transportation method was set to rail between Ports and IWHs, only trucking has been used due to not having rail service in between these nodes (it was also redundant to send goods to distant locations). In Model 1, the warehouses that supply eastern regions tend to be closer to the LA-LB Port. However, in Model 3, these warehouses are located closer

to NY-NJ Port; and mainly they in regions which offer cheaper warehousing. If consolidation of warehouses is allowed, a modification can be made to the logistics network by supplying Region 22 and 23 directly from IWH 2.

The difference between Model 3 and Model 4 is the transportation methodology. By considering proposed warehousing locations for Model 3, we figure out that the proposed transportation method between the Ports and IWHs was trucking with 40-foot containers. For Model 4, this was trucking with 53-foot containers. Despite the fact that trucking with 53-foot containers is generally cheaper than trucking with 40-foot's, Model 4 suggests locating IWH 2 to Region 22, where warehousing cost is high. When we analyzed this abnormality, we noticed that there was a glitch in the 40-foot trucking costs of NY-NJ Port and IWH 2 pair. This difference is in favor of transporting goods with 40-foot trucking between NY-NJ Port and Region 21, and 53-foot trucking between NY-NJ Port and Region 22. Therefore, the proposed logistics network formed accordingly.

For the second set of experimentations,

Two modifications were made on these models. The first one is the change of Port from LA-LB to NY-NJ. The second one is the implementation of a set of constraints to the objective function of the OptQuest model. "Type A" models were constructed based on this new set of constraints which is restricting to have more than one RWH at any given region. There are also "Type B" models which are practically the same as the previous set. The results are given in Table 5.2 and 5.3 below.

	Model 1	Model 12	
Constraints	Туре-В	Туре-А	Туре-В
Port of Entry	LA - LB	NY- NJ	NY- NJ
Mode of Transp.	Rail	Rail	Rail
IWH 1	7	7	7
IWH 2	13	21	21
RWH 1	7	7	7
RWH 2	10	10	10
RWH 3	15	16	16
RWH 4	16	21	21
RWH 5	16	19	16
RWH 6	15	18	19
Total Cost	1.195293639	1.186357251	1.184473355

<u>Table 5.2</u>: Data of the second set of experimentations, Group $1^{(3)}$

Before interpreting the data provided for this experimentation set, we need to keep in mind that 60% of the overall market is supplied by the IWH 2, and the rest is by IWH 1. Therefore, in any given scenario, we are expecting that being closer to the high demand areas will be more favorable regarding to the overall cost of the logistics network. When we solely compare the total cost of Model 1 and Model 12-B, we notice that serving the entire Market through NY-NJ Port is more desirable (At this point, note that even though we have fixed the location of the IWH 1, the latter scenario is more promising than the first one on account of the given input data). This proposition is also valid for the Model 2 and Model 13-B pair.

⁽³⁾ Optimal assignments of IWHs and RWHs to regions

	Model 2	Model 13	
Constraints	Туре-В	Туре-А	Туре-В
Port of Entry	LA - LB	NY- NJ	NY- NJ
Mode of Transp.	Trucking	Trucking	Trucking
IWH 1	7	7	7
IWH 2	12	22	21
RWH 1	7	7	7
RWH 2	10	10	10
RWH 3	15	15	16
RWH 4	15	21	21
RWH 5	18	19	16
RWH 6	12	18	19
Total Cost	1.267873734	1.259596291	1.185321453

<u>Table 5.3</u>: Data of the second set of experimentations, Group $2^{(4)}$

As we stated before, the sole difference between Type-A and Type-B models is the restriction of locating multiple RWHs in any given region. By comparing the proposed optimum warehousing locations, we observe that restricted models consider distributing warehouses to the neighboring, low-cost regions. The effect of this restriction on the cost output of the Model 12 is an increase of 0.16%; while, for Model 13, it is around 6.27%.

For the third set of experimentations,

We have fixed the port of entry to LA-LB Port and mode of transportation to "rail" option (between Port and IWHs). With this set of experimentation, we intend to focus on warehousing cost and demand factors of the model. We defined two-level interactions.

⁽⁴⁾ Optimal assignments of IWHs and RWHs to regions

Level-1 values are based on the original input data that were presented in Chapter 4; while another set of data was derived for Level-2. Representative values for these levels are shown in Table 5.4 and 5.5, and the actual inputs for regional demand are shown in Table B.5 and B.7 in Appendix B.

			% of Tota	al Imports
[Region ID	Region Name	Level-1	Level-2

Table 5.6: Data of the third set of experimentations

By comparing Model 1 and Model 5, we observe that the import volume distribution has a significant effect on the logistics network. The alterations in locations of RWH 1, RWH 3 and RWH 4 can be presented as convincing proofs for this argument. As high demand density regions change form one model to another, RWHs tend to be located closer to these regions. This pattern can be seen in Figures 5.1 and 5.2. The Regions in these maps are colored based on the import volume distribution (percentage of demand by region).

Changes in warehousing cost also affect the optimum logistics network. Basically, when warehousing cost in a given region is increased, the model tends to locate the warehouse in neighboring regions. This pattern can be observed in Figures 5.3 and 5.4. The locations of IWH 1, IWH 2 and RWH 1 did not change from Model 1 to Model 7 due to making these locations more favorable in terms of warehousing cost.

Chapter 6

Conclusion and Future Work

For this thesis, we have focused our attention on the logistics networks of an importer company. The objective was to develop a tool to help companies in making their warehouse location decisions and understand certain factors that has crucial effect on this decision. We have developed a simulation template for Arena which is capable of modeling most of the important aspects of this logistics network which is consisting of ports, international warehouses, regional warehouses and customer market. OptQuest Software was linked to the simulation model to solve the optimization problem. The objective function is seeking an optimum warehouse networking solution that minimizes the overall cost of the logistics network. We have analyzed the effect of certain factors on the optimization of logistics networks, such as, port of entries, transportation means, import volume distributions and warehousing costs.

In most of the logistics network solutions, we observed that the warehousing location assignments follow a branching pattern starting from the port of entry and stretching towards downstream echelons. The segments of these branches, meaning distance between Port-IWH or IWH-RWH pairs, get longer or shorter depending on the transportation cost inputs of the model. Basically, in order to minimize the overall transportation cost, the optimization model searches a solution to balance the cost ratio between these segments. As a big portion of the imported goods is being consumed in Eastern Regions through IWH 2, using only LA-LB Port and then supplying these Regions by mini-land bridge drastically increases the total cost of the model. According to the data used in the model, it could be advised to utilize either two ports and supply each IWH separately; or, at least, set NY-NJ Port as the only port of entry.

According to the proposed model and its inputs, warehousing cost and import volume distribution appear to be important factors for selecting warehouse locations in the logistics network. If there are multiple potential neighboring regions, the optimization model normally chooses the low-cost region. However, when these regions are similar to each other according to the warehousing cost, the model seeks for a location which is closer to the high-demand regions.

6.1 Future Work

Even though this tool is capable of handling multiple scenarios without any change in its logic, we can still suggest additional improvements and modifications for further, more detailed studies. In this section, we are going to mention about these suggestions starting from upstream echelons to downstream echelons.

6.1.1 <u>Product Origin:</u>

- Vessel scheduling.
- Loading and unloading processes that includes resources.

6.1.2 <u>Ports:</u>

- Simulating congestion in and around the port area. This would be one of the most crucial improvements in the logic due to its severe effect on retrieving containers from the port and transporting them to required places, on time.
- Including processes that effect transit time and require certain resources. For example, container loading/unloading, security checks, movements inside the port.
- Vessel and rail scheduling.
- Implementing operation hours.
- Utilization of services like customs house brokers and simulating their optional effects on the system.
- Leaving Port as a variable; so that the port of entry can also be optimized together with the warehousing network.

6.1.3 <u>Warehouses:</u>

- Adding structure constraints that will be used to keep warehouses in certain limits. This approach might be helpful for restraining the model to come up with more realistic warehouse capacity results.
- Including value added processes and their effect on logistics networks.
- Some other way of inputting warehousing cost that might be based on the amount of inventory or turnover ratio.
- Implement other inventory control policies such as economic order quantity with reorder level and safety-stock.

6.1.4 Customers (Regions):

- Ordering mechanism should be relaxed by implementing various demand distributions and ordering intervals.
 - Allowing triangular distribution for entering demand quantities this provides a better fit to the ordering logic.
 - Instead of generating demand daily, other options should be presented such as weekly or every other day.

6.1.5 General Suggestions:

- Instead of having a pull system, in which supply is triggered by the amount of demand, implement a combination of pull and push system, in which goods are pushed to the market.
- Include the effects of changes when goods are being transferred from one transportation method to another. For example, delays between unloading containers from train and loading them to trucks.
- Implementing emergency scenarios, backup plans. Lets say when rail service is down, can you transport goods by trucking; or, if a certain warehouse cannot supply demand of the lower echelon, can it be supplied from another location.

Appendix A

Calculations for Table 4.1:

- 1 TEU is equal to 1,169 cu foot.
- As an assumption stated by Leachman (2005), pipeline and warehouse inventories are valued 25% and 50% more than declared values to Customs, respectively.
- Annual interest rate is accepted as 35%.
- Lost sales cost is assumed to be 1/3 of the commodity value at warehouse.

Pipeline Cost (daily) = $1.25 \times 1169 \times 1000$ X Declared Value $\times 0.35 / 365$

Safety-Stock Cost (daily) = $1.50 \times 1169 \times 1000$ X Declared Value $\times 0.35 / 365$

Lost Sales Cost = $1.50 \times 1169 \times \text{Declared Value} / 3$

Regions and assumed warehousing sites are as follows:

- Seattle-Tacoma Region: including Washington, Oregon, Idaho and Montana Warehousing location is assumed to be in Fife, WA.
- Oakland Region: including Wyoming, 50% of Colorado, 67% of Utah, 34% of California, and 33% of Nevada. Warehousing location is assumed to be in Tracy, CA.

- LA-LB Region: including Arizona, New Mexico, 66% of California, 67% of Nevada, 33% of Utah, and 50% of Colorado. Warehousing location is assumed to be in Ontario, CA.
- Minneapolis Region: including North Dakota, South Dakota, Minnesota and 50% of Wisconsin. Warehousing location is assumed to be in Rosemount, MN.
- Kansas City Region: including Kansas, Nebraska, Iowa and Missouri. Warehousing location is assumed to be in Lenexa, KS.
- Dallas Region: including Oklahoma and 50% of Texas. Regional distribution center assumed to be in Midlothian, TX.
- Houston Region: including Louisiana, Mississippi and 50% of Texas. Warehousing location is assumed to be in Baytown, TX.
- Memphis Region: including Arkansas, Tennessee and Kentucky. Warehousing location is assumed to be in Millington, TN.
- Chicago Region: including Illinois, Indiana, Michigan and 50% of Wisconsin.
 Warehousing location is assumed to be in Joliet, IL.
- 10) Atlanta Region: including Alabama, Georgia, Florida and 50% of South Carolina.Warehousing location is assumed to be in Duluth, GA.
- Columbus Region: including 50% of Ohio. Warehousing location is assumed to be in Springfield, OH.
- Cleveland Region: including 50% of Ohio and 25% of New York. Warehousing location is assumed to be in Chagrin Falls, OH.
- Pittsburgh Region: including West Virginia and 50% of Pennsylvania. Warehousing location is assumed to be in Beaver Falls, PA.

- 14) Charlotte Region: including North Carolina and 50% of South Carolina.Warehousing location is assumed to be in Salisbury, NC.
- Norfolk Region: including Virginia. Warehousing location is assumed to be in Suffolk, VA.
- Baltimore Region: including Maryland, DC and Delaware. Warehousing location is assumed to be in Frederick, MD.
- Harrisburg Region: including 50% of Pennsylvania. Warehousing location is assumed to be in Allentown, PA.
- New York Region: including New Jersey, Connecticut and 75% of New York.
 Warehousing location is assumed to be in East Brunswick, NJ.
- Boston Region: including Rhode Island, Massachusetts, New Hampshire, Vermont and Maine. Warehousing location is assumed to be in Milford, MA.

Appendix C

The preparation of Table C.3,

We retrieved transportation rates from "Table 18: Transportation Rates per Cubic Foot" of Leachman's (2005) Study. This Table represents estimated rates per cubic foot of shipment from Shanghai to the selected destinations through alternative ports of entries. This data also includes direct dray cost through ports to nearby regions (shown in Table C.1). We assumed that 90% of this cost is due to shipping of goods from Shanghai to ports of entries and the rest is for drayage, taxes, fees, etc. As shipping costs are expected to be constant regardless of destination region and mode of inland transportation, we used this assumption to come up with inland transportation costs.

Port of Entry	Destination Region	Direct Dray Cost
Houston	Houston	1.21
LA-LB	Los Angeles	1.06
Norfolk	Norfolk	1.28
NY-NJ	New York	1.33
Oakland	Oakland	1.09
Seattle-Tacoma	Seattle-Tacoma	1.02

Table C.1: Direct dray costs from ports to nearby regions (\$ per cubic foot)

For example, direct dray cost is \$1.06 for LA-LB Port to Los Angeles Region. 90% of this cost makes \$0.954. We deduct this amount from direct rail data in order to calculate inland rail costs. The resulting data is shown in Table C.3 which represents rail transportation rates for 40-foot container (2395 cu foot).

Table C.4 and C.5 represent distance between ports, warehouses and regions (for any combination). These values were gathered directly from Google Map; and Table C.5 data were used to calculate inputs specified at Table C.6, C.7 and C.8.

Transit time calculations (Table C.6),

We have assumed that a truck can travel 16 hours every day and on average 50 miles per hour. Moreover, due to possible delays, a day or two is added to the transit time values depending on the distance between port-destination pair. An example is given below, If distance = 853 miles

Transit Time =
$$\frac{853}{50 \times 16}$$
 = 1.06625

As it is less than or equal to 1, add an additional day and round off to the nearest integer. Therefore, *Transit Time* = 2.

For a distance of 2218 miles, the first division is greater than 1 (around 2.77); therefore, consider 2 more days for possible delays and round off to the summation to the nearest integer. This gives 5 days for transit time.

The preparation of transportation costs between Ports and WHs in Table C.7 & C.8,

This is similar to the calculations for Table C.3. However, instead of using direct rail data, direct truck and trans-load truck data are used to calculate trucking cost between Ports and warehouses. Cost data between warehouses were explained in Chapter 4.

General Note: First 4 location numbers are assigned for Ports, the rest (starting from 5, up to 23) are for warehouses.

		1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23
	TDistRail	LA-LB	NY- NJ	SA	SE-TA	Seattle-Tacoma	Oakland	Los Angeles	Minnea.	Kansas City	Dallas	Houston	Memphis	Chicago	Atlanta	Columbus	Cleveland	Pittsburgh	Charlotte	Norfolk	Baltimore	Harrisburg	New York	Boston
1	LA-LB	100	100	100	100	4	100	100	8	6	6	6	6	6	8	8	8	8	9	9	9	9	9	9
2	NY-NJ	100	100	100	100	9	10	9	5	5	6	8	5	3	4	3	3	3	4	3	100	100	100	100
3	SA	100	100	100	100	11	11	10	7	6	4	5	3	4	1	4	5	5	3	3	3	5	4	3
4	SE-TA	100	100	100	100	100	100	4	5	8	8	10	8	6	9	8	8	9	10	9	9	9	9	9

Note 1: Some of these listed port-destination pairs do not have available railing service; in order to keep simulation logic free of errors, we assigned high-values (100) to these pairs.

As a result, possibility of railing between these pairs is eliminated.

Note 2: Highlighted transit times represent values that are not supplied by the Leachman's Study. Instead of leaving them blank, we accepted transit times of the reverse directions.

Table C.3: Assumed cost values for inland rail movements of 40-foot containers (\$)

Table C.8: Assumed costs for inland 53-foot truck movements (\$)

Note 8: Even if it is not logical to specify distance in between Ports (and from WHs to Ports), it was required to assign values to these cells. Red-highlighted cells represent this type of inputs. Note 9: Seattle-Tacoma (SE-TA) Port was not used; therefore, this Port's data is not present. Minimum possible values are assigned to these values.

Appendix D

Below, we provide detailed information about the logistics template that we have developed for Arena.

General Information and Assumptions:

- Each node is represented by a location number. This number should be set via node's interface and it should be unique for each port, IWH, RWH and region. Generally, this input is being used as an index for certain variables.
- Rail service is not implemented for IWH-RWH and RWH-Region pairs.
- Some variables should be set through Variables Module at Basic Process Template of Arena. They can be classified into two groups:
 - 1. General cost and duration variables.

These variables are required for simulation purposes. They define general cost and duration parameters between locations.

TDistOrigin(i, j): duration for shipments from Product Origin location i to Port at j.

TDistRail(i, j): duration for rail shipments from Port location i to IWH at j.

TDistTruck(i, j): duration for truck shipments from location i to j.

ShippingOriginCost(i, j): cost of shipments from Product Origin location i to Port at j.

RailCost(i, j): cost of rail shipments from Port location i to IWH at j.

40TruckCost(i, j): cost for 40ft container shipments from location i to j.

53TruckCost(i, j): cost for 53ft container shipments from location i to j.

<u>Note</u>: TDistOrigin and ShippingOriginCost variables define duration and cost of shipments independent of the transportation method (trucking, rail, ocean). As a result, these variables should be updated according to the transportation method defined at the Product Origin.

2. Variables required for optimization purposes.

These variables are used to control variables of the OptQuest model. There is no need to input these variables unless we seek to optimize a logistics network.

LocVar(i, 5): location variables -location number, facility value, delay per order, ordering and handling costs-for international and regional warehouses.

LN_I_k: location number for kth IWH.

LN_R_k: location number for kth RWH.

- Liability of products is transferred to the importer company when goods are received at the Port of Entry.
- Every node in the logistics network is operational non-stop throughout the year.

DOE Control

This module has been added to the template for the purpose of experimental design. It facilitates data manipulation between simulation runs.

• It controls certain cost and time inputs of a model.

- For example, if the shipping cost is \$1000 for an origin-destination pair and the cost multiplier for ocean transportation set to "1.5" through this module, then the shipping cost will be taken as \$1500 for that simulation run.
- Entered values should be non-zero real numbers. This is crucial especially for the transportation time multipliers.

DOE Control		×				
Transportation Cost Multipliers	Transportation Time Multipliers	Inventory Cost Multipliers				
<u>O</u> cean: 1	<u>O</u> cean: 1	Warehousing: 1				
<u>I</u> rucking: 1	Irucking: 1	Pipe Line: 1				
<u>B</u> ail: 1	<u>R</u> ail: 1	Safety Stock: 1				
These multipliers will be used to adjust input data.						
	Γ	OK Cancel <u>H</u> elp				

Figure D.1: Dialog box of DOE Control module

Seasonality

Seasonality effects on sales volume should also be considered in logistics networks. For this reason, seasonality module has been implemented into the template. Generally, it is used for creating demand variability between consequent seasons.

• Although this module was built to handle different seasonality inputs; for the time being, it supports only bi-periodic seasonal input.

Seasonality Input 🛛 🗙

Figure D.2: Dialog box of Seasonality module

- If Seasonality Module is going to be used, the simulation start date and time should be set to January 1st (any year, preferably 2008) at 12:00 am.
- These cycles are based on calendar year. Therefore, the first cycle of the year starts on January 1st and the last cycle ends on December 31st. For the implemented six-month cycle, 1st cycle starts on January 1st and 2nd cycle starts on July 1st. These cycles takes place one after the other throughout the simulation run.
- Demand intensities entered are used to adjust demand quantities for each region.
 This logic is quiet similar to the DOE control.
- In order to prevent uncontrollable inventory fluctuations at warehouses, keep variability of the demand intensity within 0 to 3.

Simulate

- This module controls certain replication parameters of the simulation run such as warm-up period, length and number of replications.
- "Simulation cost calculation" input is being used to calculate a desired cost output value to the output file. For example:
 - Origin 1_OveallCost ⁽¹⁾ + Port 1_OverallCost + IWH 1_OverallCost + RWH 1_OverallCost
 - This part should not be left blank.
- The date variable window next to Simulate object should be syncronized with the simulation start date and time.
- Other inputs (project title, analyst, date) are reference information that will be shown in the output file.

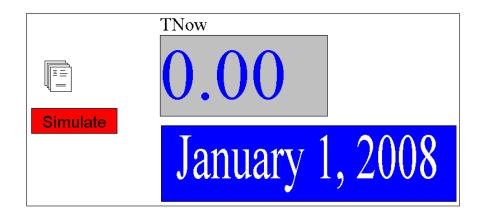

Figure D.3: Seasonality module on canvas

⁽¹⁾ There is a typo in the model regarding this variable. It was supposed to be "OverallCost".

Figure D.4: Dialog box of Simulate module

Product Input

This module is for inputting pipeline, safety-stock and lost sales costs for products.

- The template is limited to 50 products.
- The module is also responsible for inputting container capacities in terms of twenty-equivalent units (TEU). Three different container capacities are considered; and they are hardcoded into the template:

- 20 ft standard volume container = 1163 cu ft = 1 TEU
- 40 ft standard volume container = 2395 cu ft = 1 FEU
- 53 ft standard volume container = 3830 cu ft

Therefore,

40ft = 2.05 TEUs, assume **40ft container = 2 TEUs**

53ft = 3.29 TEUs, assume **53ft container = 3 TEUs**

Figure D.5: Dialog box of Product Input module

Region

Region modules represent the customer base of the company. According to the implemented logic in the template, a given market can be represented with multiple regions which is quiet similar to the clustering methodology.

- Every Region is associated with a regional warehouse and only this warehouse can supply that region. This connection is set via Region's dialog box.
- Demand inputs are based on normal distributions. If the generated value is negative, then that number will be replaced by zero (this was set as a precaution to generating negative values).
- Orders are generated on daily basis and sent to the assigned RWH.
- If an order is partially satisfied, the unsatisfied amount is accepted as lost sales.
- There are multiple variable windows associated with this module. These windows are kept in order to follow up the simulation run beneath the user view. Mean and standard deviation of the demand distributions are shown by "Mean i" and "Std i" windows; last ordered quantities are displayed by "Order i" (only the first three products' information are shown, the rest are being kept internally).
 "DestinationStation" and "LocNo" show the station number of the assigned RWH and the location number of the region, respectively.

DestinationStation		Order 1	Mean 1	Std 1	Lost Sales 1
0.00		0.00	0.00	0.00	0.00

Figure D.7: Dialog box of Region module

Regional WH

- Regional Warehouses reside between International Warehouses and Regions.
- A RWH can only be supplied from one IWH.
- If associated IWH cannot satisfy the overall order, then inventory positions for those products will be adjusted accordingly.
- Multiple parameters can be entered by using RWH interface, shown in Figure
 D.9. Most of them are all self explanatory except "inventory control" input.
 - There are three different options (manual input, Type-1 and Type 2 calculations) to set inventory control parameters to the model. According to the selected option, the interface asks for alternative inputs that are shown in Figure D.9 and D.10. Check Section 3.1.1 for the equations of Type-1 and Type-2 calculations.

- When seasonality effects on demand are allowed, different inventory control parameters should be set for each season. This is important for adequately supplying demand of the lower echelon. This variability in the model can be provided by either Type-1 or Type-2 option. Simply put, if one of these options are selected, inventory parameters of the RWH are updated based on the estimated demand from the lower echelon prior to the beginning of each cycle (25th day of the last month of the previous cycle).
- When an order arrives:
 - Demand is supplied depending on the available stock.
 - If an order is partially satisfied, the unsatisfied quantity is accepted as lost sales. This might be converted into dollar value if lost sales costs are set via product input module.
 - Demand quantities are based on TEUs; the whole supply is consolidated into 40-foot and/or 53-foot containers and sent to the destination. The priority is sending goods with 53-foot containers. 40-foot containers are used if remaining supply cannot fill more than 2/3 of the 53-foot container.
 - The whole supply is assumed to be sent by a single convoy entity which is (possibly) composed of multiple trucks.
- There are some important variable windows next to RWH object:
 - Order up to level (OuL i), re-order level (RoL i), pipeline cost (PL Cost i), safety-stock cost (SS Cost i), supply quantity of the last order (Supply i), estimated demand of lower exhelon (Est DMND i) and standard deviation of demand (Std Dev i).

- Overall Cost includes facility, handling, ordering, trucking, pipeline (TotPipeCost), safety-stock (TotSSCost) and lost sales costs.
- Pipeline cost is referring to the transit inventory cost in between IWH and RWH.

Figure D.10: Dialog boxes of RWH module with Type-1 and Type-2 options

International WH

- International warehouses reside between Ports and RWHs.
- IWH module is quiet similar to RWH's, except its ordering mechanism.
 - IWHs send their orders to Product Origin nodes and receive supply through Ports. Each IWH can be supplied through one Origin-Port pair.
- Pipeline cost is referring to the transit inventory cost in between Port and IWH. This is due to the assumption about the transfer of liability of products at the Port of Entry.
- There is no lost sales cost associated with IWH module. If RWH's demand is unable to be satisfied (or it can be partially satisfied), a notification will be sent to the RWH. This notification will adjust inventory position parameters. It is

responsible for lowering the inventory parameter by the magnitude of unsatisfied order quantity. With the updated inventory parameters, RWH will check its inventory in the next review period and place order for required products.

Figure D.13: Dialog box of IWH module with Type-1 and Type-2 options

Port

- Ports reside between Product Origin and IWHs. They are responsible for debarkation of containers coming from Product Origin.
- Two transportation methods -trucking and rail- have been implemented in this module. The modeler is allowed to choose either one of these methods which can be set by three different options.
 - "Trucking" option is accepted as the basic transportation method. When this option is selected, all duration and cost inputs for 40-foot and 53-foot trucking should be entered to the model.
 - "Rail" option is set as an alternate to trucking. Even though only rail transportation is selected for a port, in reality this service may not be

available for some Port-IWH pairs. For this reason, rail transportation is relaxed by allowing transportation of goods by trucking whenever rail transportation is not defined for a Port-IWH pair.

- "Truck or rail" option allows the model to choose between trucking or rail transportation depending on the duration of transportation between each Port-IWH pair.
- In the template, there is no scheduling for rail transportation. Variability for train arrivals might be set together with other delays at the port through "delay per order" and "std dev of lead time".
- Cross-docking to 40-foot containers is assumed to be done at every Port regardless of the transportation method; however, cross-docking to 53-ft containers is left as an option for the modeler and it is valid with only "trucking" option. Thus, for "rail" option, only 40-foot containers will be used to transport merchandise to IWHs; this is independent of the available transportation method.
- Overall cost is equal to total cost per order (TotalCost/Order), total container fee (Total Cont Fee) and total transportation cost.

Figure D.15: Dialog box of Port module

Product Origin

In order to simulate a source for products, we introduced Product Origin module into the template. This module is responsible for supplying overall demand in the model.

- Origin modules are accepted as infinite source of product. Therefore, they have the capability of supplying any amount without backordering or losing sales. A supporting assumption for this reasoning is the concept of blanket orders. In other words, the importer company is assumed to be making agreements with its vendors to secure forecasted amount of merchandise.
- The whole supply is assumed to be sent by either a single entity -a ship or a trainor a convoy entity, which is composed of multiple trucks.

- 40-foot containers are used for transportation to Port of Entries.
- Overall Cost is based on total cost per order (Total Cost/Order), total container fee

(Total Cont Fee) and total shipping cost.

Appendix E

Model 4 Outputs

In this section, we introduce a summarized version of the output values of our models; and as an example, we have picked Model 4's simulation-optimization outputs. Figure E.1 and E.2 represent screenshots from OptQuest software. Our intention to show this figure was to give an idea about the optimization procedure. According to these figures, the optimization problem has found its optimal answer at the 407th simulation. Nonetheless, we kept this optimization model running for another 30,000 combinations of different logistic network scenarios (Generally, we kept every model running not less than 15,000 additional combinations from the last found best solution).

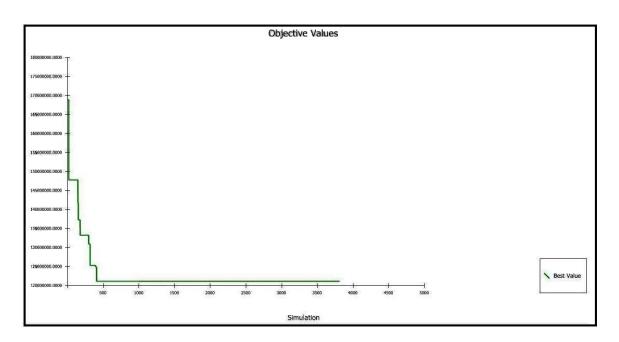

Figure E.1: OptQuest chart representing expected cost values

Figure E.2: Numerical output of the optimization model during the iterations

- "LN_I_x" stands for the location of IWH x.
- "LN_R_y" stands for the location of RWH y.
- Units of demand, inventory parameters and lost sales are in TEUs.
- Units of cost values are in dollars.
- Satisfaction levels are between 0 and 1.
- Units of time parameters are in days.
- Abbreviations:
 - "Inv" stands for on-hand inventory level,
 - "SS" stands for safety-stock level.

Below, we represent the outputs of simulation model for the optimum (warehousing location) solution achieved from the OptQuest.

	Value
